A Note from "Mom":

If only our doctor told us about
Nutramigen sooner!

My son is, today, a completely different,
happy baby. He is playful, talkative, and
has a better appetite. He has started
to take an afternoon nap peacefully
instead of crying himself to sleep.

Thank you!
Deborah and Michael W.
North Carolina

The Sooner the Better!

WHEN YOU CHOOSE A PROTEIN HYDROLYSATE, THERE'S NOTHING AS GOOD AS...

NUTRAMIGEN®

"OUCH"

For "minor league" injuries, there's a better choice than aspirin

When your 6- to 14-year-old patients need pain relief for minor injuries, Junior Strength **TYLENOL**® acetaminophen should be your first choice. Clinical studies have proven **TYLENOL**® to be every bit as effective as aspirin for pain relief,¹ with a superior safety profile.² Together with the recommended regimen of rest, ice, compression, and elevation, it's the better choice than aspirin for the pain of minor self-limiting injuries.³

Junior Strength **TYLENOL**® can also help reduce underdosing because children need only half as many

160 mg caplets as 80 mg chewables. They're coated for easier swallowing, too.

So next time a junior patient says "Ouch!", recommend local therapy for the inflammation, and make your first choice Junior Strength **TYLENOL**® acetaminophen for the pain.

With one application...

Rx or OTC

The best treatment to kill lice and nits

Up to 99% effective with one application

Clinical studies prove Nix™ kills lice and nits and protects against reinfestation better than a single application of Kwell® and Rid®.* Only Nix

More patients lice-free at day 14 with Nix

vs 1% lindane ¹		vs Kwell ²		vs Rid ³	
99%	85%	98%	76%	96%	62%
Nix	lindane	Nix	Kwell	Nix	Rid

Rid labeling requires a second application at 7-10 days. Carson et al demonstrated 100% efficacy for Nix and 93.5% efficacy for Rid when used according to manufacturer's labeling.⁴

provides 14-day protection against reinfestation—with one application—and no evidence of CNS toxicity as reported with lindane overexposure.⁵

Nix FOR LICE[®]
CREME RINSE

permethrin 1%

Call 1-800-FOR-LICE
to report head lice outbreaks

Please see adjacent page for brief summary of prescribing information.
Rid® is a registered trademark of Pfizer, Inc., Phlpharmecs Division.
Kwell® is a registered trademark of Reed & Carnrick. NI-139

NIX[®] FOR LICE[®]

CREME RINSE

permethrin 1%

PEDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus* var. *capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus* var. *capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combing of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: Teratogenic Effects: Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp (especially behind the ears and on nape of the neck). Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combing of nits is not required for therapeutic efficacy, but may be done for cosmetic reasons or to meet school "no nit" policies. A nit comb is provided.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz. weighing 56 g. (NDC-0081-0780-81)

Store at 15°-25°C (59°-77°F).

HOUSE BASED PEDIATRICIANS (HBPs)

Huntington Memorial Hospital of Pasadena, California, a major affiliate of the University of Southern California School of Medicine, is seeking to hire four board eligible/certified pediatricians by July 1, 1989 to cover its 34-bed pediatric floor. These four house-based pediatricians (HBPs) will provide in-house coverage that traditionally would have been provided by pediatric interns or residents.

Founded in 1892, Huntington Memorial Hospital is a 606-bed non-profit medical center that serves the communities of the San Gabriel Valley of Los Angeles County. The total service area population of the San Gabriel Valley is approximately two million people. The Hospital offers a tertiary Infertility Center, Perinatal High-Risk Unit, a Neonatal ICU and renowned ECMO Center, a comprehensive Pediatric Center and a Pediatric ICU.

The compensation is competitive with the HMOs or other salaried positions in the area: \$70,000 annual salary; health insurance (medical, dental, vision); life insurance (\$50,000 term life); accidental death & dismemberment (\$50,000); paid 3-week vacation; and a \$1000 annual CME fund.

Those interested should send their CV and inquiries to Edgardo L. Arcinue, M.D., Head, Department of Pediatrics, 100 Congress Street, Pasadena, CA 91105; (818) 397-8688.

EDITORIAL POLICY

The JOURNAL is meant to provide physicians in all specialties who practice pediatric medicine a complete and accurate synthesis of all current research developments and clinical topics pertinent to their practice, as well as an open forum for dialogue on scientific, educational, ethical, and humanistic issues of concern to any intellectual committed to the practice of pediatrics.

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

Instructions for Authors

NEW MANUSCRIPT PROCEDURE

On Jan 1, 1988, *AJDC* initiated a new procedure. Manuscripts submitted to *AJDC* will NO LONGER BE RETURNED, except in the case of accepted manuscripts or those undergoing author revision. Original artwork and photographs will be returned.

General Information.—Please send manuscripts and correspondence by first-class mail (do not use registered, certified, or express mail) to the Editor, Vincent A. Fulginiti, MD, *AJDC*, Dean's Office, Room 1529, Tulane University, School of Medicine, 1430 Tulane Avenue, New Orleans, LA 70112. All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Reprints are shipped six to eight weeks after publication. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Conforming with all of the steps listed below will facilitate the editorial processing of your manuscript.

Step 1.—Cover Letter.—All manuscripts must be accompanied on submission by a cover letter giving the name, address, affiliation, and telephone number of the corresponding author. The letter must include ALL of the following statements SIGNED BY ALL AUTHORS (ORIGINAL SIGNATURES):

1. **Copyright Release.**—"In consideration of the American Medical Association's taking action in reviewing and editing this submission, the author(s) undersigned hereby transfer(s), assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that this work is published by the AMA."

2. **Statement of Affirmation.**—"This manuscript has not been published anywhere in any language and is not under simultaneous consideration by another publication. This manuscript is original and ALL authors have seen and approve of its contents."

3. **Financial Disclosure.**—List all affiliations with or financial involvement in organizations or entities with a direct financial interest in the subject matter or material of the research discussed in the manuscript (eg, employment consultancies, stock ownership) OR include a statement disclaiming any such involvement. All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosures appropriate for publication. All accepted manuscripts become the permanent property of the publisher (AMA) and may not be published elsewhere without written permission from the AMA. After publication certain articles may appear in translation in the foreign-language edition(s) of *AJDC*.

Step 2.—Manuscript Format.—All articles submitted should have the following features:

1. Four copies of the manuscript should be submitted; three are for transmission to referees and one is to be retained in the editorial office. We prefer an original and three copies.

2. Manuscripts should be typed in triple-spaced format on heavy-duty white bond paper, 21.6×27.9 cm (8½×11 in) with 2.5-cm (1-in) margins. Do not use justified right margins.

3. Title should be no more than 75 characters.

4. Authors should be limited to six, all of whom have contributed to the study and manuscript preparation, are familiar with its substance, and are able to defend its conclusions.

5. The title page should give full names, degrees, and academic affiliations of all authors, address for request of reprints, and, if the manuscript was presented at a meeting, the organization, place, and exact date on which it was read.

6. Writing style should conform to proper English usage and syntax; consult the *American Medical Association Manual of Style*, available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202.

7. Abstract should be limited to 135 words or less.

8. Each table should be typed, with a title, on a separate sheet of paper, with each line, including headings, double-spaced. Continuations should be on a second sheet with all headings repeated.

9. Use Systeme International (SI) measurements throughout the manuscript.

10. Illustrations should be high-contrast, glossy prints, in quadruplicate, unmounted and untrimmed; lettering should be legible after reduction to column size. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed on the back of each illustration. Do not write directly on the print.

Magnification and stain should be provided for histologic sections. Full-color illustrations should be submitted as 35-mm, positive color transpa-

encies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies or color prints. Fee is \$400 for up to six square-finished color illustrations that fit on one page. A letter of intent to pay the fee must accompany submission.

All photographs in which there is a possibility of patient identification should be accompanied by a signed statement of consent from both parents (or guardians). Covering eyes to mask identity is not sufficient.

11. References should be listed in order of their appearance in the text, type double-spaced, and in AMA format. Please follow the exact order of information and punctuation in the examples below.

Journal Articles: Sell EJ, Gaines JA, Gluckman C, Williams E. Persistent fetal circulation: neurodevelopment outcome. *AJDC*. 1985;139:25-28.

Books: Krmpotic-Nemanic J, Kostovis I, Rudan P. Aging changes of the form and infrastructure of the external nose and its importance in rhinoplasty. In: Conly J, Dickinson JT, eds. *Plastic and Reconstructive Surgery of the Face and Neck*. New York, NY: Grune & Stratton; 1972:84-91.

Unpublished data, personal communications, or manuscripts "in preparation" or "submitted" should not be included in the list of references. Such material, if essential, may be incorporated in the body of the article.

Authors are responsible for the accuracy of the references.

12. Investigations involving human subjects require a specific statement in the "Methods" section that an appropriate institutional review board approved the project and/or that informed consent was obtained from both legal guardians and/or child, if appropriate.

13. Illustrations and tables from other publications should be suitably acknowledged, with written permission from publisher and author. Brief acknowledgements to specific contributors directly involved in the content of the manuscript may be placed at the end of the text, before the references. General acknowledgements will be deleted.

Step 3.—Special Departments.—Criteria for several special departments are given below.

1. **The Pediatric Forum.**—This is the place for comment, criticism, observations, and discussion of "issues of current concern and importance for children's health," in addition to letters that comment on articles in previous issues of *AJDC*. The Editor reserves the right to conduct review of and to edit all submissions. THE READER SHOULD SUBMIT TRIPLE-SPACED COPY CLEARLY MARKED "FOR PUBLICATION" AND SIGNED BY ALL AUTHORS. REFERENCES, IF INCLUDED, SHOULD CONFORM TO THE USUAL AMA FORMAT. Copyright assignment, signed by all authors, must accompany the original submission.

2. **From Research to Relevance.**—PURPOSE: To focus on significant research that has a high probability of being translated into clinical usefulness.

3. **Educational Interventions.**—PURPOSE: To share information concerning any educational efforts in the broad field of pediatrics.

4. **Sports Medicine.**—PURPOSE: To provide current information related to the medical needs of young athletes, as pertinent to counseling young athletes and their parents regarding sports participation and practices contributing to the health maintenance of the athlete, as well as current concepts in the prevention, diagnosis, and treatment of sports-related illnesses and injuries.

5. **Picture of the Month.**—Submissions should be sent directly to Murray Feingold, MD, National Birth Defects Center, Kennedy Memorial Hospital, 30 Warren St, Brighton, MA 02135, and should conform to the format for original articles in terms of the text, references, and illustrations.

6. **Radiological Case of the Month.**—Submissions should be sent directly to Beverly P. Wood, MD, University of Rochester Medical Center, 601 Elmwood Ave, PO Box 648, Rochester, NY 14642. Submissions should conform to the format for original articles in terms of the text, references, and illustrations.

Author's Checklist

- ____ 1. Cover letter with name, address, and telephone number of corresponding author.
- ____ 2. Copyright transmittal, affirmation, and financial statements signed by ALL authors.
- ____ 3. Original typed manuscript plus three copies.
- ____ 4. Triple-spacing; double-spacing for tables and legends.
- ____ 5. Right margins UNJUSTIFIED.
- ____ 6. Title 75 characters or less.
- ____ 7. Abstract included.
- ____ 8. References in proper format, cited in numerical order.
- ____ 9. Four sets of illustrations.
- ____ 10. Four sets of legends for illustrations.
- ____ 11. Proper consent forms for patient photographs.
- ____ 12. Permission forms for illustrations previously published elsewhere.

The Pediatric Forum

This department of AJDC is reserved for comment, criticism, observation, and discussion of "issues of current concern and importance for children's health." The Editor encourages our readers to express themselves on a variety of topics and issues. Further, we encourage the submission of unique and brief clinical and scientific observations that do not fulfill the criteria for original articles.

The Diagnosis of Group A, β -Hemolytic Streptococcal Pharyngitis in the Office Setting

Sir.—I read with interest the article in the January 1989 issue of *AJDC* by Taubman et al¹ reporting that a latex agglutination test for direct detection of group A streptococci had a sensitivity of 89.4% and a specificity of 85.7%. Several points in the "Results" and "Comment" sections of the report, however, are of concern.

The authors observed that the sensitivity reported by Roddey et al² was significantly lower than that found in their own study, a difference they attributed to "... the difference in the experience of the people performing the latex test." Another very possible explanation is that, in the study by Roddey et al, sheep blood agar cultures were incubated for 36 to 48 hours if negative after 12 to 24 hours, in contrast to the 18 to 24 hours of incubation reported by Taubman et al. Increased recovery of group A streptococci from sheep blood agar cultures incubated for a second day has been reported to range from 5% to 26%.³⁻⁶ The sensitivity as reported in the very thorough study by Roddey et al, therefore, may more truly reflect the product's performance compared with a carefully performed culture in a pediatrician's office.

The specificity of the latex method (85.7%) as reported in the study of Taubman et al is considerably lower than that reported for the same product in most other studies, as reviewed by Facklam.⁷ This indicates the possibility that some of the "false-positive" results obtained by Taubman et al just might, in fact, have been true-positive results in the face of false-negative culture results.

Taubman et al stated that they compared the latex agglutination test performed in the office of pediatricians

with throat cultures performed in the same office. However, the sensitivity and specificity figures that they reported for the product (calculated from data in Table 1 of the report) come from a comparison of latex test results from the physicians' office with culture results obtained after the cultures were sent to their reference laboratory. The comparison of results of the latex test with those from the pediatrician-read office cultures was not given in the report.

The information on performance of group A streptococcal antigen detection products as presented by Taubman et al is helpful and serves as another point of reference. It appears to be premature, however, to recommend completely replacing a competent culture with this kind of antigen assay until improvements in the assay are made by the manufacturer or until another assay with a well-documented improved sensitivity is marketed.

In Reply.—A major purpose of our study was to evaluate both latex tests and cultures when both tests were performed by pediatricians. It had been our practice to read culture results the morning after specimens were plated, a maximum of 24 hours. Since a survey we conducted of pediatricians and family practitioners in the Delaware Valley area showed this was also the practice of the vast majority of physicians polled, we did not alter the practice for the study. However, the cultures were incubated for at least an additional 24 hours before they were read by the reference laboratory. The sensitivity of the latex agglutination test we reported of 89.4% was determined using the results of the reference laboratory reading of the cultures. Therefore, the cultures were incubated for the same length of time before reading as the cultures in the study by Roddey et al and this may not be used to explain the difference in the sensitivity of the latex test or the specificity as suggested by Dr Kellogg.

Direct comparison of the latex test with pediatrician-read office cultures was not done since either could be incorrect. To compare the two tests one must see how accurate each is when compared with "the gold standard," which, in this case, was the reference laboratory reading of the cultures. This was, in fact, done in our study (Tables 1 through 3).

We clearly do not advocate replacing throat cultures with a latex assay in all situations. For the practitioners, the decision depends greatly on the

quality of the alternative, which, for most, are office cultures. Given that even when done under the most optimal conditions and care the sensitivity of office cultures is about 90%, we are concerned that in many offices the sensitivity is much lower. When that is the case, the office latex test may be the superior alternative.

Assessment of Neurodevelopmental Outcome in Surfactant-Replacement Therapy

Sir:—Surfactant-replacement therapy has achieved a position of great prominence recently in the pediatric literature. The article by Vaucher et al¹ in *AJDC* on the neurodevelopmental outcome of infants treated with human surfactant appears, like the surfactant recipients, to be premature. Two major problems are apparent. First, although the two clinical trials of surfactant replacement were carefully designed, the study population was reduced both by deaths and by those "unavailable for follow-up." Although the authors may have examined differences between those patients who returned for follow-up and those who did not, they did not present such information in their article. With the smaller sample sizes, the possibility of type II error increases and the authors' conclusions of "comparable neurologic and developmental outcome during early childhood in human surfactant-treated and control infants" are not thoroughly supported by their data. Type II error involves not rejecting the null hypothesis when it is false.² In other words, if we conclude that a treatment does *not* make a difference when it indeed *does*, we are guilty of type II error. The probability of making a type-II error (β) is a

function of both sample size and the α level chosen as "statistically significant." If, in the study by Vaucher et al,¹ we combine children with mild, moderate, and severe developmental delay, we find an adverse outcome in approximately 60% (11/17) of the controls and 45% (10/22) of the surfactant-treated children. If we assume that a traditional $\alpha = .05$ was used, given the difference observed and the sample size, $\beta > .5$.³ Thus, a 15% difference would be considered not significant. Only with 98 patients in both the control and study groups would a difference of this size have a 50% chance of being recognized as statistically significant. More recently, retrospective sample-size calculations based on risk reduction have been described by Detsky and Sackett.⁴ The advantage of this retrospective sample-size calculation is that knowledge of the frequency of events (eg, neurodevelopmental delay) in the control and study populations often results in more accurate and smaller sample sizes. If we use the charts provided by Detsky and Sackett⁴ for retrospective sample-size calculations, 15 patients are needed in each group to detect even a 25% risk reduction (or risk increase as the case may be). To detect a smaller change in risk, such as 15%, larger sample sizes are needed. Thus, only if children with mild, moderate, and severe developmental delay were combined and only if a minimum 25% change in risk were considered clinically significant would Vaucher and colleagues be able to draw a "true-negative" conclusion.

This brings us to the second problem, that of the different developmental tests used and the time of administration. The authors employed a variety of developmental assessment tools that vary somewhat in the measures employed. The Knobloch-Gesell Developmental Screening Inventory consists of selected items from the Gesell Developmental Schedules and provides ratings of adaptive, gross motor, fine motor, language, and personal-social characteristics.⁵ The Griffiths Mental Developmental Scales equally weigh five similar areas (locomotor, personal-social, hearing and speech, eye and hand, and performance) to derive a total score.⁶ The Bayley Scales of Infant Development provides two scores—a mental score (Mental Developmental Index) and a motor score (Psychomotor Developmental Index).⁶ The authors also men-

tion use of the Stanford-Binet Scale for children 36 to 48 months of age but only one child was tested! It is unclear to me why one developmental test was not uniformly employed for a given age range throughout the population. More disturbing is the fact that the authors have reported "only the single most recent test result for each child." Consequently, the assessment reported may have occurred as early as 6 months' or as late as 24 months' adjusted age. Recent studies^{7,8} have suggested that scores achieved by prematurely born children on some of these tests frequently are not stable over this time period. Over a longer period, children with an early diagnosis of cerebral palsy often experience resolution or lessening of motor impairment.⁹ Developmental processes may help one child to improve and overcome dystonia of prematurity while another child's spastic diplegia may become more pronounced and cause increasing dysfunction over time. Comparison of developmental test results over such a broad age range is at least unscientific. It is thus very difficult to accept the authors' conclusion of comparable neurodevelopmental outcome in surfactant-treated and control populations. Although surfactant-replacement therapy holds promise for increasing survival rates for very premature infants, the study by Vaucher et al does not dispel the possibility that the potentially greater number of survivors may include a larger proportion of severely impaired children.

In Reply.—We appreciate Dr Langkamp's concern that the widespread use of surfactant-replacement therapy among very-low-birth-weight infants with surfactant deficiency might result in an exchange of increased neurodevelopmental morbidity for decreased mortality caused by respiratory distress syndrome. Although a larger patient population would be ideal to exclude a type II error conclusively, our follow-up data, based on a randomized, controlled trial of human surfactant replacement, did not indicate substantial differences in major neurologic or developmental sequelae, such as cerebral palsy or severe mental retardation, between surfactant recipients and placebo-treated infants receiving conventional ventilation. We cannot yet exclude differences between the two groups in later sequelae, such as communication disorder, attention-deficit disorder, perceptual-motor abnormalities, or learning disability. While a 100% follow-up rate is desirable, this is difficult to accomplish in most regions of the United States given family mobility, high frequency of low socioeconomic status, and the lack of universal access to health care. Among Finnish infants, for whom health care services are universally available and centralized regardless of family locale the follow-up rate was nearly 100%, and we were encouraged to find neurodevelopmental outcomes similar to those reported in American infants. As we noted, a longer-term study may reveal differences based on the disparate demographic characteristics of the two patient groups.

Each of the developmental tests employed in our study assesses cognitive and motor function and is standardized for specific age groups within each population. Because different examinations were used, the data were compared in terms of deviation from the test mean rather than as numeric scores. A single assessment was used for each infant to avoid bias resulting from differing numbers of examinations per child. We used the most recent age-adjusted test results for each child to improve the correlation between this early assessment of development with later estimates of intellectual function.¹⁻³ While the age

range of infants tested in our study was broad, the median adjusted age at examination was 24.5 months.

Our study, like previously published ones, does not address the issue of longer-term neurodevelopmental outcome. Indeed, mild neuromotor abnormalities detected during the first year of life are often transient, although they may be markers for later developmental problems at school age, and infants with cerebral palsy identified at 12 to 24 months of age may be neurologically normal in later childhood. Rather, our purpose was to determine whether infants treated with surfactant demonstrated more adverse early neurological or developmental outcome, as was recently reported by Dunn and coworkers in Toronto, Canada.⁴ Our data demonstrate no significant differences in 2-year outcome between surfactant-treated and control groups. A larger and longer-term follow-up study of our diverse patient populations is currently under way to exclude definitively any differences in neurodevelopmental outcome between infants receiving human surfactant and those treated only with traditional ventilatory techniques. Our data support the use of exogenous surfactants as investigational agents in very-low-birth-weight infants. To answer definitively questions regarding long-term efficacy of this approach to respiratory distress syndrome, additional randomized, controlled clinical trials, not case registries, are needed. Clearly, longer-term follow-up studies must be incorporated in the design of ongoing clinical trials of a variety of surfactants.

Are 'Hot' Ears Really Hot?

Sir.—Recordings from the tympanic membrane appear superior to those obtained from most other sites commonly used for measuring body temperature.¹⁻⁷ Infrared determinations of temperature have been shown to be fast and accurate^{1,2} and have been used to monitor localized increases in temperature from a variety of causes and sites.¹ We used a commercially available device that measures tympanic membrane temperature (FirstTEMP, Intelligent Medical Systems Inc, Carlsbad, Calif) to explore the effect of otitis media on that temperature. We assumed that patients with unilateral otitis media would display a difference in ear temperature measurements that reflected the magnitude of the local effect of the otitis, ie, that the normal ear would reflect the core temperature and the infected ear would reflect the local increase because of the infection.

Patients and Methods.—Unilateral otitis media was defined as an acute illness with a normal ear opposite a red tympanic membrane that was either immobile or bulging. Sixty-two such patients underwent bilateral infrared measurements to compare the normal ear with the infected ear. Uninfected ears had temperature recordings ranging from 36.1°C to 40.3°C with a mean of 37.58°C, while the infected ear temperatures ranged from 36.3°C to 40.3°C with a mean of 37.67°C. Figure 1 displays the plot of temperatures from infected ears on the y axis vs normal ears on the x axis. The correlation between the infected and normal ears was significant and positive ($r = .91$; $r^2 = .83$; $P = .0001$). The regression equation was as follows: infected ear equals 0.903 times the normal ear plus 0.07. The average (\pm SD) difference between the two ears was $0.094^\circ\text{C} \pm 0.38^\circ\text{C}$. Figure 2 shows the frequency distribution of the difference between infected and uninfected ear temperatures.

Comment.—The center for thermoregulation in the hypothalamus responds to its vascular perfusion temperature, presumably directing the changes that generate the events that modify in core temperature.^{3,4} For a patient at a thermic steady state, febrile or otherwise, a number of sites have been used to estimate core temperature. Those sites—cutaneous, axillary, sublingual, rectal, esophageal,

Fig 1.—Scattergram of temperatures of infected vs normal ears.

Fig 2.—Frequency distribution of the distribution of the difference between infected and normal ears.

and central venous—have varying levels of patient discomfort and technical difficulty.¹⁻⁶ The technically simpler sites suffer from perfusion difficulties that reduce their response to change and therefore limit usefulness in the thermally unstable patient. Areas such as the tympanic membrane that are well perfused and that share vascular supply with the hypothalamus are ideal for temperature sampling.^{3,6} Initial tympanic temperature recorders were sealed in the canal close to the tympanic membrane, but discomfort and complications limited their use to special cases, ie, anesthetized patients and astronauts.⁷ This problem is solved with measurement of infrared radiation from the tympanic membrane.

Infrared energy radiating differentially from various sources has been used for military "night vision," for night photography, for crop or weather analysis from satellites, and for temperature recording from a distance in scientific studies.¹ Infrared energy radiating from the ear is used clinically to measure body temperature and has been shown to correlate well with other measurements of core temperature.^{1,2} In fact, the technique offers

theoretical and practical advantages over more peripheral measurements. It is obtained quickly and easily and is well tolerated; cross-contamination is less likely; and the response time to temperature change is virtually instantaneous.^{1,2}

Since local heat is a classic sign of infection and since otitis is common in children, we proposed that an ear with unilateral otitis media would yield higher temperature determinations than in the normal ear. Localized infection of one middle ear should not alter perfusion of the contralateral normal ear. The normal ear should reflect the perfusion of the hypothalamic thermoregulatory center. The temperature increase in the infected ear compared with that in the normal ear should then disclose the local thermal effect of the otitis. Using the FirstTEMP device, we found the infected ears to be $0.094^{\circ}\text{C} \pm 0.38^{\circ}\text{C}$ hotter than the uninfected ears, and we propose that the local heat effect of otitis media is of that order. This difference was not large enough to interfere with the clinical use of ear infrared measurements in patients with otitis media as an approximation of core temperature. We conclude that "hot" ears are only approximately 0.1°C hotter than normal, ie, that hot ears are not very hot.

Cholecystectomy in Sick Cell Anemia

Sir.—In the July 1988 issue of *AJDC*, Malone and Werlin¹ reported the re-

sults of preoperative transfusion before elective cholecystectomy at the time of diagnosis of cholelithiasis in children with sickle cell anemia. Our own practice supports the conclusions of this study.

From 1976 to 1988, 240 children have been seen at the sickle cell clinic. Over the last 10 years, 24 children with sickle cell anemia (mean age, 10.5 years) underwent surgery for cholelithiasis in the Pediatric Surgery Unit at Centre Hospitalier Régional et Universitaire de la Guadeloupe. An annual ultrasonography study detected gallstones in 9 patients.

Fifteen children had a history of recurrent abdominal pain. Of these, 10 were admitted because of acute complications (4 patients with acute cholecystitis, 1 with biliary pancreatitis, and 5 with choledocol stones, with jaundice and cholangitis).

From 1979 to 1985, 13 children underwent surgery without preoperative transfusions. Seven of these children experienced postoperative complications (5 developed pneumonia, 1 developed osteomyelitis, and 1 developed wound sepsis). The preoperative mean hemoglobin level was 76 g/L, with a range of 60 to 100 g/L.

From 1985 to 1988, 11 children received preoperative transfusions and underwent surgery without any postoperative complications. The mean preoperative hemoglobin level was 128 g/L, with a range of 110 to 150 g/L.

The protocol we used is straightforward. If the total hemoglobin level is greater than 85 g/L and less than 120 g/L, the child receives a 10-mL/kg transfusion with packed red blood cells 1 day before surgery. If the total hemoglobin level is less than 85 g/L, a 20-mL/kg transfusion with packed red blood cells is given 2 days before surgery. Before transfusion, one third of the transfused blood is sampled from another vein. If the total hemoglobin level remains less than 120 g/L, an additional 10-mL/kg transfusion of packed red blood cells is given the day before surgery.

Drug Usage Among Adolescents: A Survey From a Pediatric/ Adolescent Practice

Sir.—Studies have documented alcohol and other drug usage among the adolescent population. In 1985, in a study of over 17 000 high school students, 75% admitted to trying alcohol, 60% marijuana, and 16% cocaine.¹ Because these statistics, along with other statistics from similar studies, involve a cross section of the population, the percentages of drug usage by adolescents in a given practice might be very different. Depending on many factors, including demographics, socioeconomic status, ethnic population served, and geographic areas (urban vs rural), the figures in any pediatric practice may be dissimilar to the figures quoted.

In dealing with the problem of drug usage/abuse in an adolescent population in one's own practice, it might be beneficial to know what the statistics are in regard to drug usage in the population being served. In the process of obtaining information about the deliberate intoxication of children and pets by adolescents, I obtained general information concerning drug usage.² The study population consisted of an upper-middle-class population in a suburb of San Diego, Calif.

Subjects and Methods.—My practice is that of a pediatrician in a large multispecialty group who has had fellowship training in adolescent medicine. The statistics are from a survey that was conducted between March and June of 1987. The group practice serves as a health maintenance organization as well as a private practice setting.

One hundred three male adolescents and 100 female adolescents between the ages of 12 and 18 years completed an anonymous questionnaire. The questionnaire was completed in the examining room without the parents being present. These patients were being evaluated for illnesses as well as receiving routine health maintenance evaluations. They were not being evaluated for drug-related problems. The questionnaire asked if they had ever tried alcohol, marijuana, or other drugs, and if they used such drugs on a regular basis. The definition of "regular basis" in this study was defined as once a month or more. Tables 1 and 2 provide the statistics in regard to drug usage by age and sex.

Comment.—As expected, the older the adolescent, the more likely he or she used alcohol or other drugs, either on a trial or regular basis. Surprisingly, however, female adolescents began experimenting with alcohol and a variety of drugs at an earlier age than

did male adolescents and continued to do so up until 18 years of age. It is not known whether this trend continues beyond this age since we did not survey patients older than age 18 years.

Do female adolescents experiment with drugs at an earlier age because of their earlier age of onset of puberty with all of the physical and emotional turmoil that puberty entails? Are female adolescents being exposed to drugs at an earlier age because of our societal dating patterns (usually involving an older male adolescent rather than one of the same age as the female adolescent)? Does this now mean that female adolescents have a higher risk-taking potential for drug usage than male adolescents? Certainly, it has been traditionally taught that boys display more risk-taking behavior than girls, but does this occur at a later age? Is this now changing in our society at least as drug usage is involved? These questions cannot be answered by this small, limited study.

Another disturbing point of this study involves the resurgence of the use of LSD. This drug was popular in the early 1960s and seems to be again gaining popularity. Will we start seeing more problems related to intoxication with this substance? Perhaps by knowing what age group use drugs and what drugs are being used by the adolescent patients in our own practices, we can become more successful at intervention. However, it must be emphasized that the information obtained from this population of adolescents may not apply to other pediatric/adolescent practices. Since female adolescents (at least in my practice) are experimenting with drugs at an earlier age than male adolescents, it might be beneficial to target girls at a younger age for preventive drug programs. Unfortunately, statistics on nicotine use were not obtained, although this substance clearly belongs in the category of drug abuse.

Reconsideration of IgM-Enriched Intravenous Immunoglobulin for Neonatal Sepsis

To the Editor.—In the article by Haque et al¹ in the December 1988 issue of *AJDC*, the authors concluded that mortality from neonatal sepsis (suspected or proved) was significantly reduced in a group of 30 infants treated in a prospective, randomized trial with IgM-enriched intravenous immunoglobulin (Pentaglobin, Biotest Pharma, Frankfurt, West Germany) in addition to antibiotics compared with a control group of 30 infants who were treated with antibiotics alone.

Their conclusion of a statistically significant ($P < .001$) reduction in mortality between the treated and control groups was based on the use of Student's *t* test for statistical analysis. Is there some rationale that makes use of the Student *t* test the appropriate test for analysis of these outcome data?

As outcome is a discrete and not a continuous or numerical parameter, a *t* test, which is a parametric test of the difference in means between two samples or two groups, is not the proper test to apply to this analysis. Rather, a nonparametric test is indicated, as outcome can be categorized as the proportion of infants in each group who lived vs those who died. Reorganization of their Table 2 into a 2×2 contingency table would appear as follows:

Group	Lived	Died
Control (n = 30)	24	6
Immunotherapy (n = 30)	29	1

Using Fisher's Exact Test, because the expected frequencies in some of the cells are less than 5,² and a two-sided test, because there is no strong basis for predicting which way the test should turn out, the level of significance is $P = .10$ (Statpak 4.1, Northwest Analytical Inc, Portland, Ore). The failure to reach statistical significance at $P < .05$ using Fisher's Exact Test in this case may be due to a β

error from too small a sample size; that is, the failure to find a significant difference in outcome among treated and control infants, if the treatment did in fact make a difference, could be overcome by studying a larger population of infants.

However, if the Fisher Exact Test is applied to evaluate differences in outcome among only infants with proved sepsis, then $P = .40$.

While the idea to use IgM-enriched intravenous immunoglobulin to treat neonatal sepsis is an interesting variant on the idea of using standard, commercially available intravenous immunoglobulin for the same purpose, Haque et al have not provided convincing data regarding the efficacy of the preparation studied. Further studies are warranted before adopting IgM-enriched intravenous immunoglobulin as part of a therapeutic armamentarium against neonatal sepsis.

In Reply.—I am grateful for Dr Hall's interest in our work. Indeed, the reason for not using the Fisher Exact Test was that our sample size was too small for each cell.

We do not claim that we have proved the efficacy of IgM-enriched intravenous immunoglobulin in the treatment of neonatal sepsis. What we have tried to show is that this modality helps in improving the outcome but needs to be confirmed by larger studies. We are now comparing intravenous immunoglobulin with IgM-enriched intravenous immunoglobulin in the treatment of neonatal sepsis.

Firearm-Associated Homicides Among Family Members, Relatives, or Friends—Ohio

IN 1985, 311 (56%) of 553 homicides in Ohio occurred among relatives or acquaintances; 191 (61%) of these 311 homicides involved the use of firearms (Federal Bureau of Investigation (FBI), unpublished data, 1985). To learn more about firearm homicide among persons who are closely acquainted, the Ohio Department of Health (ODH), Division of Epidemiology interviewed offenders involved in homicides occurring between 1982 and 1985 that met the following six criteria: the homicide 1) occurred in Cleveland, Cincinnati, Columbus, Toledo, Dayton, or Akron; 2) occurred between family members, relatives, or friends; 3) was committed with a firearm kept in the household; 4) victim and offender were greater than or equal to 18 years of age; 5) occurred in or within the immediate vicinity of a residence; and 6) was not secondary to another crime. The primary purposes of the investigation were to describe demographic characteristics of the offenders and to identify situational or environmental factors related to the homicide.

Using records from the Ohio State Department of Corrections and Rehabilitation and police records from Cleveland, Cincinnati, and Columbus, investigators identified 105 homicides that met the above criteria. Of these, interviews were completed with 50 (48%) offenders. Of the 55 offenders who were not interviewed, 37 (67%) could not be located, 12 (22%) refused to participate, and three (5%) had died. Three (5%) interviews were not completed for other reasons.

Since the Ohio Homicide study included only a subset of firearm-associated homicides that occurred among family members, relatives, or friends, selected offender characteristics were compared with Ohio data from the FBI. The distribution from the Ohio homicide study approximates Ohio estimates from the FBI for median age

of the offender and type of firearm used in the homicide (FBI, unpublished data, 1985). However, in the Ohio homicide study, offenders were less likely to be male and less likely to be white.

Offenders' responses varied widely as to their perception of the single immediate cause of the homicide. Forty percent responded that some type of threatened (30%) or actual (10%) physical abuse was occurring just before the incident, regardless of whether the victim or the offender initiated the abuse. Ten percent suggested that alcohol and/or drugs was the immediate reason for the incident. Other reasons for the incident included "jealousy," "money," or "the general stresses of living together" (10%), "accidental" (12%), "other" (10%), or "unknown" (18%).

Handguns were the type of firearm used in 76% of the homicides. Less than half the offenders reported owning the firearm; only 26% reported that the weapon was purchased from a licensed dealer. Fifty-six percent of firearms were kept in the bedroom; 96% were always kept in the household in which the homicide occurred, and the remaining 4% were usually kept in the household. Self-protection was the most commonly reported (56%) purpose for obtaining the firearm.

Sixty-four percent of the firearms were always kept loaded, and at least 64% were always kept in an unlocked location. Forty-four percent were always kept loaded and in an unlocked location. Thirty-eight percent of the firearms had been owned less than 1 year; 66% had been owned ≤ 6 years.

Alcohol was reported to have been consumed before the incident by 62% of the offenders, and alcohol and/or drugs, by 88% of the offenders and/or victims. Thirty percent of the offenders had the firearm in their immediate physical possession just before the

incident; 54% reported drawing a firearm or some other weapon first, and 22% reported the victim drew a firearm or some other weapon first. Thirty-eight percent believed they could not have resolved the situation without the firearm, and 22% responded that the victims "dared" them. Forty-eight percent reported they did not intend to shoot the victim when they drew the weapon. Forty percent indicated that the victim was approaching them when the gun was fired, and 48% fired the weapon within 15 seconds of brandishing it. Seventy percent of the offenders reported never practicing shooting firearms; 50% recalled that their parents had owned a firearm during their childhood. Seventy-four percent indicated that just before or during the incident they did not consider that they could go to prison for using a gun.

CDC Editorial Note: This investigation by the ODH helps describe the problem of firearm-associated homicide in Ohio. Homicide is the fourth leading cause of years of potential life lost before age 65 in the United States and fifth in Ohio¹ (ODH, unpublished data, 1987). In 1985, 59% of all U.S. homicides involved relatives and acquaintances.² In Ohio, between 1979 and 1986, 63% of all homicides were committed with a firearm (ODH, unpublished data, 1988).

The findings in this investigation should be interpreted with caution because the sample size was limited and restricted to homicides in six urban areas and because the sample size was further reduced as a function of the number of offenders who could be included in the study. In addition, this study investigated homicides between family members, relatives, or friends, and the results may not be generalizable to other types of homicide.

However, the results from this investigation are useful in planning future investigations of possible risk

factors for firearm-associated homicide among family members, relatives, or friends. If confirmed by future research, these findings may represent possible avenues for intervention to prevent firearm-associated injuries.

Four areas of study have been identified for further efforts in developing effective strategies to prevent firearm-associated injuries: 1) collection of information on the magnitude, characteristics, and costs of the morbidity and disability caused by firearms and

on the types of firearms that inflict these injuries; 2) determination of the number, type, and distribution of firearms in the United States; 3) conduct of epidemiologic studies that quantify the individual risks of injury associated with the possession of firearms; and 4) evaluation of interventions related to firearms. Pursuit of such research strategies should improve the scientific base of information needed for further research and prevention efforts.

Influenza Vaccine Composition Recommendation for the 1989-90 Season

During the 1988-89 influenza season, influenza type B has predominated in the United States but has cocirculated with type A(H1N1) and A(H3N2). Elsewhere in the Northern Hemisphere, type A influenza has generally predominated, with both influenza A(H1N1) and A(H3N2) cocirculating.

Antigenic analysis of type A(H1N1) viruses from outbreaks indicates that most strains are closely related to the U.S. vaccine strain, A/Taiwan/1/86. The antibody induced by this vaccine component reacts well with the recently circulating type A(H1N1) viruses.

As in last season, type A(H3N2) viruses continue to be heterogeneous. Some isolates resemble the current vaccine strain A/Sichuan/2/87, but most are better inhibited by antiserum to the A/Shanghai/11/87 reference virus. In addition, patients vaccinated with A/Sichuan/2/87 vaccine consistently had lower antibody responses to the A/Shanghai/11/87 strain than to the vaccine strain.

Most influenza B strains isolated this season, particularly in the United States, are similar to the current vaccine component, B/Victoria/2/87. However, a new variant was identified in Asia; B/Yamagata/16/88 is an example of the variant. This strain was first seen in the People's Republic of China in August 1987 and circulated in Japan, Hong Kong, Singapore, Taiwan, and

Thailand from February 1988 to January 1989. The antibody induced by the current B/Victoria/2/87 vaccine component is poorly reactive with the B/Yamagata/16/88 strain.

Based on these and other data, the World Health Organization (WHO) has recommended that the trivalent influenza vaccine for use in the 1989-90 season contain the following components: type A(H3N2), A/Shanghai/11/87-like antigen, and type B/Yamagata/16/88-like antigen and retain the type A(H1N1) component of the current vaccine. This decision has been ratified by the Food and Drug Administration's Vaccine Advisory Panel.

WHO Collaborating Center for Influenza, Influenza Br and Epidemiology Office, Div of Viral Diseases, Center for Infectious Diseases, CDC (MMWR vol 38, No. 11).

CDC Editorial Note: Influenza type A viruses are classified into subtype on the basis of two antigens: hemagglutinin (E) and neuraminidase (N).

Three subtypes of hemagglutinin (H1, H2, H3) and two subtypes of neuraminidase (N1, N2) are recognized among influenza A viruses that have caused widespread human disease. Immunity to these antigens, especially the hemagglutinin, reduces the likelihood of infection and the severity of disease if infection occurs. However, over time there may be enough antigenic variation (antigenic drift) within the same subtype that infection or vaccination with one strain may not induce immunity to distantly related strains of the same subtype. Antigenic variation occurs with influenza B viruses, although no subtypes are known to exist. For these reasons, major epidemics of respiratory disease caused by new variants of influenza continue to occur. The antigenic characteristics of current strains provide the basis for selecting virus strains included in each year's vaccine.

The manufacturing, quality control, and distribution process involved in producing about 30 million doses of influenza vaccine in the United States require many months to complete. Therefore, the decisions on which strains to include in the vaccine formulation for the 1989-90 influenza season were to be completed by late March to early April of 1989. Specific recommendations by the Immunization Practices Advisory Committee will be available later this spring.

FAMILY VIOLENCE

**Learn about the sources,
symptoms and treatment of
this American epidemic.**

From drug use to sexual abuse, all the facts about family violence—and what you as a physician, mental health professional or administrator need to know—will be addressed at the AMA's comprehensive Conference on the Prevention of Family Violence and Victimization. This multi-disciplinary conference, emphasizing current research, policies and practices

involved in the diagnosis and treatment of family violence, includes workshop topics on: The cycle of abuse; spouse, elder and child abuse; the relationship of drugs and alcohol to family violence; and legal and policy issues.

The Editorial Board Speaks . . .

George W. Brown, MD

George has been a most valuable member of our board. He often characterizes himself as a "drudge," "maven," or "curmudgeon," but he is anything but these descriptors to the Editor. George has the facility of making statistics understandable to the rest of the world, a tremendous asset to the Editorial Board and Editor. In addition, he has the uncanny knack of delving into a report and identifying and analyzing not only the statistical treatment, but the entire methodologic approach that the author(s) used. His comments are trenchant, utilitarian, and tinged with enough humor for authors and editors to enjoy, but not so much that the main message is diluted. In short, he is that rare person, a useful referee to authors of both accepted and rejected manuscripts from whom we constantly receive laudatory remarks concerning his commentaries.

PRAISE FOR USEFUL WORDS

A clerk brags to the boss, "I am *precise* in parking my car; it is always in the exact center of the space." The boss responds, "Yes, but you are not *accurate*; you often park in my space."

Some familiar and useful words may lead to discussion such as this when the words have a variety of meanings. *Precise* ordinarily means meticulous or fastidious; to a machinist it implies a closely fitted machine part. In a laboratory, *precision* may denote the exactness of a measurement (eg, glucose within 0.1 mmol/L), or it may relate to the number of significant digits used (eg, 5.1 mmol/L or 5.12 mmol/L). In some contexts *precision* implies the closeness (consistency) of repeated measurements of the same substance or object. If systematic error (bias) is present, repeated measurements may be closely clustered, but displaced from the truth, ie, they are *precise* but *inaccurate*. This was the problem with the clerk and parking.

Statisticians use *precision* to describe the dispersion or variability of a set of measurements, often expressed as the SD. Repeated measurements of the same thing should be distinguished from measurements of several things or of the same thing at different times.

Because of these vagaries of meaning, Feinstein¹ suggests that *precision* may be too ambiguous for scientific communication; he recommends *consistency*, especially in clinical situations. Others use *dependable*, which also has several meanings: durable, steadfast, predictable, credible, and so on. *Dependable* is probably not precise enough for scientific usage.

A word often seen alongside *precision* is *accuracy*. It usually means nearness to the truth, that is, to the correct value. Statisticians use *accuracy* to describe an estimate (from observations) of some parameter in relation to its true value. They also describe values that are free from systematic error (bias) as being *accurate*. There are fewer ambiguities associated with *accuracy* than with *precision*. Even if we are careful with these words, we still confront two others with varying meanings: *reliability* and *validity*.

In technical writing, *reliability* is used in three different ways. Among scholastic test-makers and psychologists,² *reliability* implies the internal consistency, the connectedness of the items in a multi-item test or psychologic instrument. It is a measure of how well the separate elements relate to the trait or factor being evaluated.

Feinstein¹ discusses the theory, development, and use of clinical rating scales, a field he has named "Clinimetrics." In pediatrics, a familiar example is the Apgar score. In psychiatry,³ there is also much concern with the inconsistencies in diagnosis and classification. In these contexts *reliability* is used in two ways: (1) Does the same observer get the same results on repeated observations of the same thing (test-retest or within-rater reliability)? (2) Do different observers see the same thing when they examine the same object or event (interrater reliability)? For example, reliability checks can be done on Apgar scoring (of the same infant) among several raters: nurse, obstetrician, anesthetist, and pediatrician. Test-retest reliability might be evaluated by comparing Apgar scores by the same observer shown the same videotape of a distressed infant on different occasions. Psychiatry has struggled with charges that diagnoses of mental illness lack both test-retest and interrater reliability.

Reliability is similar in meaning to *precision* (or *consistency*).

Validity is a kind of well-established *accuracy*; it concerns the truthfulness of the outcomes of the endeavor. *Validity* is frequently accompanied by an adjective. *Internal* validity touches on the methods, controls, randomization, and so on within an experiment used to assure that the results are credible and persuasive. But the results may not apply to subjects outside the experiment. *External* validity implies that results can be generalized from the sample studied to the population from which the sample came.

Face validity refers to the immediate "common sense" evaluation applied to a research effort. Is there surface credibility? Are the things measured sensibly related to the goals of the effort? For some of us, astrology lacks face validity. *Content* validity relates to the elements included or not included in a project. Should a test of reading skills be included in assessment of musical talent? *Construct* validity addresses the fit of the observations to already formed ideas (constructs) about the matters under study. Does the construct "intelligence" include manual dexterity? Reaction time?

In biomedical contexts, validity is often *criterion-related*; that is, do observations correspond to an established criterion or "gold standard." An academic achievement test has criterion validity if it matches actual performance, say grade point average. Physical diagnosis of a fracture has criterion validity if the roentgenogram confirms the fracture.

Criterion validity comes in two versions. *Predictive* validity concerns the accuracy with which measurement of some current element or property predicts a future characteristic. Does the Denver Developmental Screening Test⁴ at age 4 years predict neurodevelopmental integrity at age 8 years? The other version of *criterion* validity is *concurrent* validity, the extent to which a measurement of a trait or element is related to some other measurement done at the same time. Does a new quick test for streptococci agree with throat culture results?

Apgar scores have good *concurrent* validity regarding the need for resuscitation, but *predictive* validity for later impairment is poor. The validity of diagnostic tests may be described in terms of test sensitivity, specificity, and predictive accuracy, topics too complex to discuss here.

This is a sketchy look at some familiar but capricious words. They occur often in our professional literature, and their usefulness is unquestioned. For me, when professional reading begins to get tiresome, a pleasant change of pace can be achieved by poking around in the language to see how these praiseworthy words are being used—or misused.

Elevated Serum Levels of Tumor Necrosis Factor Are Associated With Progressive Encephalopathy in Children With Acquired Immunodeficiency Syndrome

Mark Mintz, MD; Robert Rapaport, MD; James M. Oleske, MD; Edward M. Connor, MD; M. Richard Koenigsberger, MD; Tom Denny; Leon G. Epstein, MD

• The cytokine tumor necrosis factor (TNF) was assayed in the sera ($n=31$) and cerebrospinal fluid ($n=26$) of children with acquired immunodeficiency syndrome, using a competitive radioimmunoassay. Elevated serum levels of TNF were found in 15 (79%) of 19 patients with progressive encephalopathy (PE), compared with 1 (8%) of 12 patients without neurologic involvement. There was a significant association of PE with elevated serum TNF levels. Conversely, of 16 patients with elevated serum TNF levels, 15 (94%) were found to have PE, and of 8 patients with serum TNF levels greater than 100 pg/mL, all 8 (100%) had PE. No association was found between cerebrospinal fluid levels of TNF and PE. Neither serum nor cerebrospinal fluid TNF levels correlated with the degree of cachexia. These data suggest that circulating TNF may be responsible for the myelin damage that occurs in human immunodeficiency virus type 1-associated PE.

(AJDC. 1989;143:771-774)

Tumor necrosis factor (TNF), a macrophage/monocyte-derived immunomediator¹ (also known as cachectin) is a cytokine that mediates both beneficial and cytotoxic events.^{2,3} It has been implicated as a mediator of septic shock,^{4,5} cachexia,^{6,7} graft-vs-host disease,⁸ and death in animals with cerebral malaria.⁹

It is also associated with a poor outcome in meningococcemia¹⁰ and pediatric purpura fulminans.¹¹ Elevated levels have been observed in human parasitic infection,¹² neoplastic disease,¹³ and adult patients with acquired immunodeficiency syndrome (AIDS) with secondary infection.¹⁴

The human immunodeficiency virus type 1 (HIV-1) has been identified as the cause of AIDS in adults and children.¹⁵ In vitro, it has been shown that HIV-1-infected mononuclear cells produce a factor cytotoxic to L929 cells, a fibroblast cell line sensitive to the lethal effects of macrophage-derived TNF.¹⁶ Supernatants from monocyte cultures of symptomatic HIV-1-infected patients produce sevenfold greater levels of TNF compared with control subjects and much higher levels than asymptomatic HIV-1-infected patients.^{17,18}

Children with AIDS often develop a progressive, debilitating encephalopathy.¹⁹ The clinical hallmarks include loss of developmental milestones or dementia and pyramidal tract signs, with the pathologic features of severe white matter degeneration, inflammatory cell infiltrates with macrophages and multinucleated giant cells,²⁰ and radiologic and pathologic features of cerebral atrophy.¹⁹ The pathogenesis of this condition has remained elusive and speculative.

Recently, Selmaj and Raine²¹ demonstrated that TNF, in vitro, led to the destruction of oligodendrocytes, which led to speculation that TNF may be involved in processes of white matter destruction. In vitro experiments have demonstrated that stimulated rat astrocytes release a cytotoxic factor that kills L929 cell targets and rat oligodendrocytes, as does recombinant human TNF

(r-Hu-TNF). Taken together, these observations suggest that stimulated astrocytes may produce TNF.²² Therefore, cytotoxic factors, such as TNF, released by HIV-1-infected invading inflammatory cells of monocyte/macrophage lineage or resident microglia, may be involved in the white matter damage associated with HIV-1 infection.^{23,26}

Many children with pediatric AIDS exhibit failure to thrive and a progressive cachexia.²⁶ It has been proposed that wasting or cachexia may also be a TNF-mediated event.⁶ Therefore, we have investigated levels of TNF in the serum and cerebrospinal fluid (CSF) of HIV-1-infected children with or without progressive encephalopathy (PE) or wasting.

METHODS

Specimens of sera ($n=31$) and CSF ($n=26$) from children with AIDS, aged 6 months to 17 years (mean, 4.1 years), stored at -70°C , were assayed for TNF; 25 specimens were matched. Specimens were collected as part of ongoing studies of HIV-1 infections in children. All of the patients fulfilled the Centers for Disease Control, Atlanta, Ga, criteria²⁷ for pediatric AIDS. Using previously described clinical criteria,^{19,20} each child was diagnosed as having either PE (22 patients provided 19 sera and 18 CSF samples), or no PE (NPE) (14 patients provided 12 sera and 8 CSF samples). Briefly, all children with HIV-1 infection at our institution were classified into one of the following three categories:

1. *Normal neurologic findings.*

2. *Static encephalopathy.*—These children had developmental delay or motor deficit that was nonprogressive and had normal brain growth. Static encephalopathies occurred frequently in our patient population prior to the appearance of HIV-1 infection and were most often due to premature birth, intrauterine exposure to drugs or other in-

fectious agents, or genetic factors.

3. *Progressive encephalopathy.*—These children had a loss of developmental milestones or intellectual abilities (19 of 22 patients with PE), progressive deterioration of motor function (21 of 22 patients), and/or impaired brain growth (20 of 22 patients). Impaired brain growth was documented by serial head circumference measurements or by serial computed tomographic scans.

Progressive encephalopathy was considered to be associated with HIV-1 brain infection. Children with static encephalopathy, and those with normal neurologic examination findings, were combined to form the NPE group.

These patients were further classified as being cachectic or noncachectic. Cachexia was defined as a weight quotient (weight age [age for which patient's weight is in the 50th percentile]/chronologic age of the patient) of less than 0.6. Patients were further subgrouped according to the presence or absence of secondary infections, defined as *Pneumocystis carinii* pneumonia, disseminated *Mycobacterium avium-intracellulare* or cytomegalovirus, *Candida albicans* esophagitis, chronic salmonellosis, pyogenic bacterial infections, cryptococcosis, or toxoplasmosis.²⁸ For comparison, controls were provided from sera and CSF from three children with inflammatory/infectious-associated neurologic illness (one patient with encephalitis and two patients with myelitis), providing four sera and five CSF samples; four children with noninflammatory neurologic disorders (acute infantile hemiplegia, functional disorder, central nervous system leukemia, and simple febrile seizure), providing three sera and four CSF samples.

A competitive radioimmunoassay (Medgenix, Brussels, Belgium; distributed by Cambridge Medical Technology, Billerica, Mass) was used for the TNF assay. One hundred microliters of rabbit antiserum, raised against r-Hu-TNF, was incubated for 18 hours at room temperature with either 100 μ L of patient serum or CSF, standard (known concentrations of r-Hu-TNF), or control. Subsequently, 100 μ L of r-Hu-TNF labeled with iodine 125 was added and incubated for 4 hours at room temperature. Antirabbit gammaglobulin, raised in goats, mixed with polyethyleneglycol, was then added (1 mL of solution), and, after a 20-minute incubation at room temperature, all the ¹²⁵I-r-Hu-TNF-antibody complex was precipitated.

After centrifugation, the polyethylene glycol-bound radioactivity was determined. A standard curve was constructed, and the TNF concentrations of the samples were determined by interpolation from this curve. Samples were run in duplicate determinations, with obvious outliers (2 of 174 determi-

Serum Tumor Necrosis Factor (TNF) Levels and Neurologic Status in Pediatric Patients With Acquired Immunodeficiency Syndrome*

Serum TNF Level	No. of Patients	
	Progressive Encephalopathy	No Progressive Encephalopathy
>50 pg/mL (elevated)	15	1
<50 pg/mL (not elevated)	4	11
Total	19	12

*Using Fisher's Exact Test, comparing the number of patients with progressive encephalopathy with patients without progressive encephalopathy with elevated TNF levels, a significant association was found for progressive encephalopathy and elevated TNF levels ($P<.001$).

Tumor necrosis factor levels in the serum and cerebrospinal fluid of children with acquired immunodeficiency syndrome. Elevated tumor necrosis factor levels are greater than 50 pg/mL; the limits of detectability are 10 pg/mL. PE indicates progressive encephalopathy; NPE, no progressive encephalopathy; C, cachexia; and NC, no cachexia.

nations) eliminated. Sample concentration determinations were obtained using a log representation of $B/B_0 \times 100$ as a function of the TNF concentration $\{B/B_0[(\text{counts of standard or sample}) - (\text{counts nonspecific})]/[(\text{counts of the zero standard}) - (\text{counts nonspecific})]\}$, and double-checked with an arithmetic representation of counts vs TNF concentrations of standards. The assay employed was standardized against known concentrations of r-Hu-TNF. The interassay and intra-assay coefficients of variation were less than 10%.

Results were expressed as picograms per milliliter. The limit of detection was 10 pg/mL, and greater than 50 pg/mL was considered elevated. Statistical analysis consisted of Fisher's Exact Test, two-tailed.

RESULTS

Among children with AIDS, elevated serum TNF levels (>50 pg/mL) were

found in 15 (79%) of 19 patients with PE, and only 1 (8%) of 12 patients with NPE. Overall, there were 16 patients with elevated serum TNF levels and 15 (94%) of 16 had PE. Of 8 patients with serum TNF levels greater than 100 pg/mL, all 8 (100%) had PE. Of the patients with PE and elevated TNF levels, 5 (33%) of 15 had a concomitant secondary infection. Using Fisher's Exact Test, PE was significantly associated with an elevated serum TNF level ($P<.001$), and, alternatively, an elevated serum TNF level was significantly associated with PE ($P<.001$) (Table).

Of 26 CSF samples, TNF was detected in 6 (33%) of 18 patients with PE and 5 (63%) of 8 with NPE (Figure). Of patients with PE, 2 (11%) of 18 had CSF TNF levels greater than 50 pg/mL, compared with 1 (13%) of 8 with NPE.

There was no significant association between CSF TNF levels and the presence of PE.

The only child in the NPE group with elevated TNF levels in serum and CSF died 5 months after the sample was obtained of a rare manifestation of HIV-1 infection, namely, leiomyosarcoma of the intestine. The brain at postmortem examination showed metastatic tumor but no inflammatory or white matter changes routinely found in children with HIV-1-associated PE.

Among patients with noninflammatory neurologic disorders, neither sera ($n=3$) nor CSF ($n=4$) exhibited elevated TNF levels (two samples of sera with undetectable levels and one sample with 45 pg/mL; two samples of CSF with undetectable levels and two samples with 30 pg/mL).

For patients with inflammatory neurologic disorders, there were four sera specimens from two patients and five CSF specimens from three patients. One patient with a diagnosis of encephalitis had no TNF elevation in the CSF. The two patients with myelitis had elevations in both the serum and CSF TNF levels. One of these patients had a varicella-associated myelitis, demonstrating a greater than twofold rise in serum and CSF TNF levels during an acute exacerbation—from 50 to 125 pg/mL in the sera, and 60 to 140 pg/mL in the CSF—and a return to undetectable levels during convalescence.

Of the 31 pediatric patients with AIDS, 11 were defined as cachectic and 20 as noncachectic. Of the cachectic patients, 7 (64%) of 11 had elevated serum TNF levels, and of the noncachectic patients, 10 (50%) of 20 had elevated levels. There were three CSF specimens greater than 50 pg/mL: two subjects were classified as cachectic, and one as noncachectic. There was no significant association between serum or CSF TNF levels and the presence of cachexia (Table).

COMMENT

The levels of TNF obtained in the HIV-1-infected children's sera are of a magnitude observed in other pathologic conditions. Scuderi et al¹² found patients with malaria and kala-azar with a mean of 119 pg/mL; Waage et al¹⁰ found that a level greater than 100 pg/mL of TNF in

patients with meningococemia indicated a poor outcome; Teppo and Maury,¹³ using a radioimmunoassay similar to the assay used in this study, demonstrated mean levels of 45 pg/mL in parasitic disease, 84 pg/mL in neoplasms, 20 pg/mL in rheumatoid arthritis, and 305 pg/mL in acute bacterial infections. Normal individuals have consistently undetectable or exceedingly low serum TNF levels.^{14,28} Likewise, we have found no elevated levels in control subjects with noninflammatory neurologic disorders.

In our present study, PE seen in pediatric HIV-1 infection was strongly associated with elevated serum levels of TNF compared with the group of patients without neurologic disease. Despite this strong association, it is noteworthy that CSF TNF levels were not consistently found to be elevated in children with PE. Likewise, for patients with other neurologic diseases, CSF TNF levels were elevated only in acute inflammatory disorders, including a dramatic increase of TNF in a patient with myelitis who experienced an acute exacerbation. This further implicates a role for TNF in demyelinating processes *in vivo*, as suggested by *in vitro* experiments.²¹

"Normal" or "elevated" levels of TNF in the CSF are not known. One might expect that normal levels would approach zero, since, in the nonpathologic state, invading macrophages are not present in the nervous system and resident immunologic cells are not activated. Thus, it is not surprising that the highest CSF levels were obtained during an acute, inflammatory myelitis, and in a more chronic, degenerative process, such as the slow PE of AIDS, elevations of CSF TNF were infrequently observed.

The collection technique (ie, the inability to immediately freeze the specimen or the age of the specimen [some specimens were 2 to 3 years old]) may have also contributed to a loss of measurable TNF activity. Thus, "elevated" levels of TNF in the CSF may be lower in magnitude compared with levels in serum and may have been found under conditions that maximize preservation of TNF activity. There may also be a dilution effect in the CSF, partially masking a locally acting effect of cyto-

kines. Evidence for the presence of TNF in the white matter could be provided by immunohistologic staining of the brain for TNF, as Breder et al²⁹ have demonstrated for interleukin 1 in the hypothalamus. Resident brain microglia, reported to be infected by HIV-1,²⁸ may be an additional source of TNF.

Tumor necrosis factor in the serum may cross the blood-brain barrier and cause myelin damage, even if only low levels are detected in the CSF. This would be consistent with the observed association of high serum TNF levels with PE. Alternatively, elevated serum levels of TNF may only reflect an advanced state of disease or result from concomitant infection.¹⁴ In this study, among patients with elevated serum TNF levels and PE, the finding of a concurrent secondary infection was not sufficient to account for the elevated levels.

Hesse et al⁶ have shown that humans can withstand a transient, marked elevation of TNF, but persistently elevated TNF levels may precipitate pathologic and adverse events.⁷ A sustained toxic effect of TNF on myelin²¹ could result in cumulative white matter damage as identified in neuropathologic studies of PE.²⁰ The toxic effects of TNF may represent excessive expression of a normally beneficial immune response due to the deregulation, by antigenic stimulation or proviral induction, of a normally tightly regulated gene.³⁰

Our present study reveals a significant association between elevated serum TNF levels and the PE seen in children with AIDS. Hence, TNF may provide the link between HIV-1 infection, inflammation, and white matter damage underlying PE. Secondary infections alone could not account for these elevations. The TNF found in the CSF bore no relationship to the presence of PE. No significant association was found between serum or CSF TNF levels and the cachexia associated with pediatric AIDS.

Further studies are needed to establish CSF norms for TNF; to prospectively measure TNF levels over time in an individual patient¹⁴ and its relationship to the course of neurologic illness in pediatric AIDS; to elucidate interactions between TNF and other cytokines, such as interleukin 1, interferon-

gamma, and lymphotoxin, in pediatric AIDS; and to assess local effects of TNF in tissues, such as the brain, which may be sites of cytokine-mediated pathology.

This study was supported in part by US Public Health Service grants AI23242 and NS25032, National Institutes of Health, Bethesda, Md (Dr Epstein).

Prognostic Factors and Life Expectancy in Children With Acquired Immunodeficiency Syndrome and *Pneumocystis carinii* Pneumonia

P 24, 242

Larry J. Bernstein, MD; Michael R. Bye, MD; Arye Rubinstein, MD

• Eighteen children with the acquired immunodeficiency syndrome (AIDS) were diagnosed as having *Pneumocystis carinii* pneumonia (PCP) by either open lung biopsy or bronchoalveolar lavage. Seven patients (39%) died during the acute illness. Alveolar-arterial oxygen gradients at the time of presentation and lactate dehydrogenase levels did not distinguish survivors from nonsurvivors. Total lymphocyte and T4 cell counts were low in children who died during the initial PCP infection but had considerable overlap with survivors. Response to phytohemagglutinin was measured in 5 of the 7 patients who died initially. In these patients, the mean phytohemagglutinin response was 1977 cpm. Of the 11 early survivors, 10 died within 27 months after PCP. Mean phytohemagglutinin response was 46 079 cpm in patients who died within 1 year, and 44 768 cpm in those who died later. Only 1 child is still alive 5 years after PCP illness. Children with AIDS and PCP infection have high initial mortality and poor long-term prognosis. Response to phytohemagglutinin is helpful in predicting who will survive initial PCP infection.

(AJDC. 1989;143:775-778)

Pneumocystis carinii pneumonia (PCP) is the most common opportunistic infection in adults with acquired immunodeficiency syndrome (AIDS), occurring in over half the patients with the syndrome.¹ In addition, it is found in over 80% of individuals with AIDS who present with pulmonary infection.² *Pneumocystis* has previously been described in children with AIDS as well,³ presenting as an acute or subacute illness with fever, cough, and gradually

increasing respiratory distress. Clinical findings include wheezing, rhonchi, increasing hypoxemia, and isomorphic elevation of the serum lactate dehydrogenase level. Radiological findings may vary from hyperaeration with clear lung fields to complete "white out" with a picture consistent with adult respiratory distress syndrome.

From 1983 to 1986, 18 children presented with documented cases of PCP. We describe the short- and long-term course for this group of children, as well as laboratory variables that may play a role in predicting prognosis.

PATIENTS AND METHODS

All patients were followed up by the Division of Clinical Allergy and Immunology of the Albert Einstein College of Medicine, Bronx, NY. Serologic tests for human immunodeficiency virus type 1 (HIV-1) were performed on all patients, and included both enzyme-linked immunosorbent assay and Western blot assay. The diagnosis of PCP was pathologically confirmed in all cases. Prior to 1985, the diagnosis of PCP was made by the demonstration of *P carinii* organisms in specimens obtained by open lung biopsy. In subsequent years, the diagnosis was usually made by the identification of *P carinii* in bronchoalveolar lavage fluid. Bronchoscopy and lavage were performed by one of us (M.R.B.). Lactate dehydrogenase determinations were obtained on a standard 12-channel serial analyzer with an upper limit of 225 U. The T-cell enumeration was performed by monoclonal staining with OKT4 and OKT8 antibodies, and analysis on a fluorescent-activated cell sorter.⁴ Mitogenic responses to phytohemagglutinin (PHA), concanavalin A (ConA), pokeweed (PWM), and staphylococcal Cowan A, were measured by the incorporation of radioactive thymidine.⁴

RESULTS

Clinical Course

Eighteen patients were diagnosed as having PCP. The diagnosis of *Pneumo-*

cystis was made in eight patients by bronchoalveolar lavage, in eight patients by open lung biopsy, and in two patients at postmortem examination. Seven patients presented before 6 months of age, and in these children, PCP was their first clinical opportunistic infection. Six other children presented by 2 years of age. Only one child presented at older than 4 years of age. All patients were failing to thrive at presentation.

Seven patients died during the acute initial hospitalization for PCP (Fig 1). Six of the 7 were intubated for respiratory distress and died of progressive cardiopulmonary failure. Of the 11 remaining children who survived the initial PCP infection, 5 were intubated but were able to be weaned off a respirator. Follow-up of these 11 children revealed that 5 died within 12 months of PCP diagnosis, 1 died within 18 months, 3 died within 24 months, and 1 died at 27 months after PCP infection. Only 1 patient is still alive 5 years after PCP infection.

Six of the initial survivors developed histologically confirmed recurrence of PCP, all within 15 months of the initial illness. None received PCP prophylaxis at the time of recurrence. Four children died during the second illness. There were two cases of histologically proved disseminated cytomegalovirus in our initial total cohort and one of these died at the time of development of PCP.

Nine children developed *Mycobacterium avium-intracellulare* (MAI) infection. The diagnosis of MAI was made preceding PCP diagnosis in two patients, at the time of PCP diagnosis in two patients, and in the months after PCP infection in five patients. *Candida* sepsis was noted in two patients. Invasive *Candida* preceded PCP by several months in one child and had responded

Fig 1.—Survival curve for 18 children with human immunodeficiency virus infection after onset of *Pneumocystis carinii* pneumonia.

to antifungal therapy long before PCP occurred. This child survived his initial PCP episode. A blood culture obtained shortly before death from a second child who died during the initial PCP episode yielded *Candida albicans*. This child was hospitalized for several weeks with multiple central lines, and his blood also yielded MAI.

In addition to recurrent PCP, factors contributing to poor outcome in the 10 early survivors included progressive MAI, progressive neuropathy, wasting syndrome, and, in 1 child, pulmonary hemorrhage secondary to idiopathic thrombocytopenia purpura. Two children died of acute pneumonitis without the identification of a pathogen.

Laboratory Findings

All patients had alveolar-arterial oxygen gradient of greater than 30 mm Hg at presentation. The range in room air PO_2 at presentation in survivors ranged from 45 mm Hg to 73 mm Hg. One additional child had an initial PO_2 value of 92 mm Hg on 35% inspired oxygen. The range of PO_2 in nonsurvivors was 34 mm Hg to 71 mm Hg at presentation. One child had a PO_2 of 87 mm Hg on 35%

inspired oxygen. Lactate dehydrogenase levels ranged from 320 to 2000 U/L with a mean of 922 U/L. There was no difference between survivors and nonsurvivors.

The mean total lymphocyte count was $1.4 \times 10^9/L$ (range, 0.4 to $2.6 \times 10^9/L$) in patients who died during the initial PCP episode. Values were $3.0 \times 10^9/L$ (range, 0.6 to $6.3 \times 10^9/L$) in patients who died within 1 year, and $3.3 \times 10^9/L$ (range, 1.0 to $6.9 \times 10^9/L$) in those surviving more than 1 year. Mean T4 cell count was $0.5 \times 10^9/L$ (range, 0.1 to $1.4 \times 10^9/L$) in nonsurvivors, $0.6 \times 10^9/L$ (range, 0.01 to $2.5 \times 10^9/L$) in patients who died within 1 year of PCP, and $1.0 \times 10^9/L$ (range, 0.2 to $1.7 \times 10^9/L$) in longer-term survivors. The PHA responses were markedly diminished in the children who died from the initial recurrence of PCP. The mean response was 1977 cpm with a range of 249 to 7006 cpm in the patients who died initially. The mean PHA response was 46 079 cpm (range, 11 687 to 103 701 cpm) in those who died within 1 year of PCP, and 44 768 cpm (range, 22 483 to 76 650 cpm) in those surviving longer than 1 year (Fig 2). While ConA, PWM, and

staphylococcal Cowan A responses were diminished in all children who died of the initial PCP infection, ConA response was decreased in 2 of 11 survivors, PWM in 6 of 11, and staphylococcal Cowan A in 6 of 9 measured.

COMMENT

Pneumocystis carinii pneumonia is associated with an acute mortality rate of 12% to 43% in adults with AIDS.^{2,5-7} Long-term survival (>3 years after PCP diagnosis) is unusual,⁸ although this may be modified with the advent of zidovudine therapy.⁹ There have been several studies in adults to determine prognostic factors for acute survival rates and ultimate life expectancy. Brenner et al¹⁰ reviewed 43 patients; an alveolar-arterial oxygen gradient of less than 30 mm Hg on presentation was found to be associated with survival. Factors correlating with decreased long-term survival included the persistence of *Pneumocystis* cysts 3 weeks after acute illness as well as the presence of marked interstitial edema on the lung biopsy specimen.

McCullough and Cole,¹¹ in a review of 62 patients, noted that if the alveolar-arterial oxygen gradient was greater than 60 mm Hg, 92% of the patients died during the acute event. Kales et al,¹² in a review of 145 patients, found several factors correlating with poor short-term survival. These included the degree of hypoxemia, the degree of hypocarbia (the lower the PCO_2 , the worse the prognosis), the elevation of lactate dehydrogenase levels, and hypoalbuminemia. In addition, the presence of additional pathogens worsened the prognosis.

Of our 18 children, 7 (39%) died during the acute PCP infection. Only 1 patient has survived longer than 27 months after PCP infection. Lactate dehydrogenase levels tend to be elevated in PCP,¹³ and did not distinguish survivors from nonsurvivors. The degree of hypoxia at presentation did not predict survival. In general, children with PCP do not present with mild disease with minimal hypoxia. All of our children had alveolar-arterial oxygen gradients of greater than 30 mm Hg. The absolute number of lymphocytes did not clearly distinguish survivors from nonsurvivors. While T4 cell counts tended to be

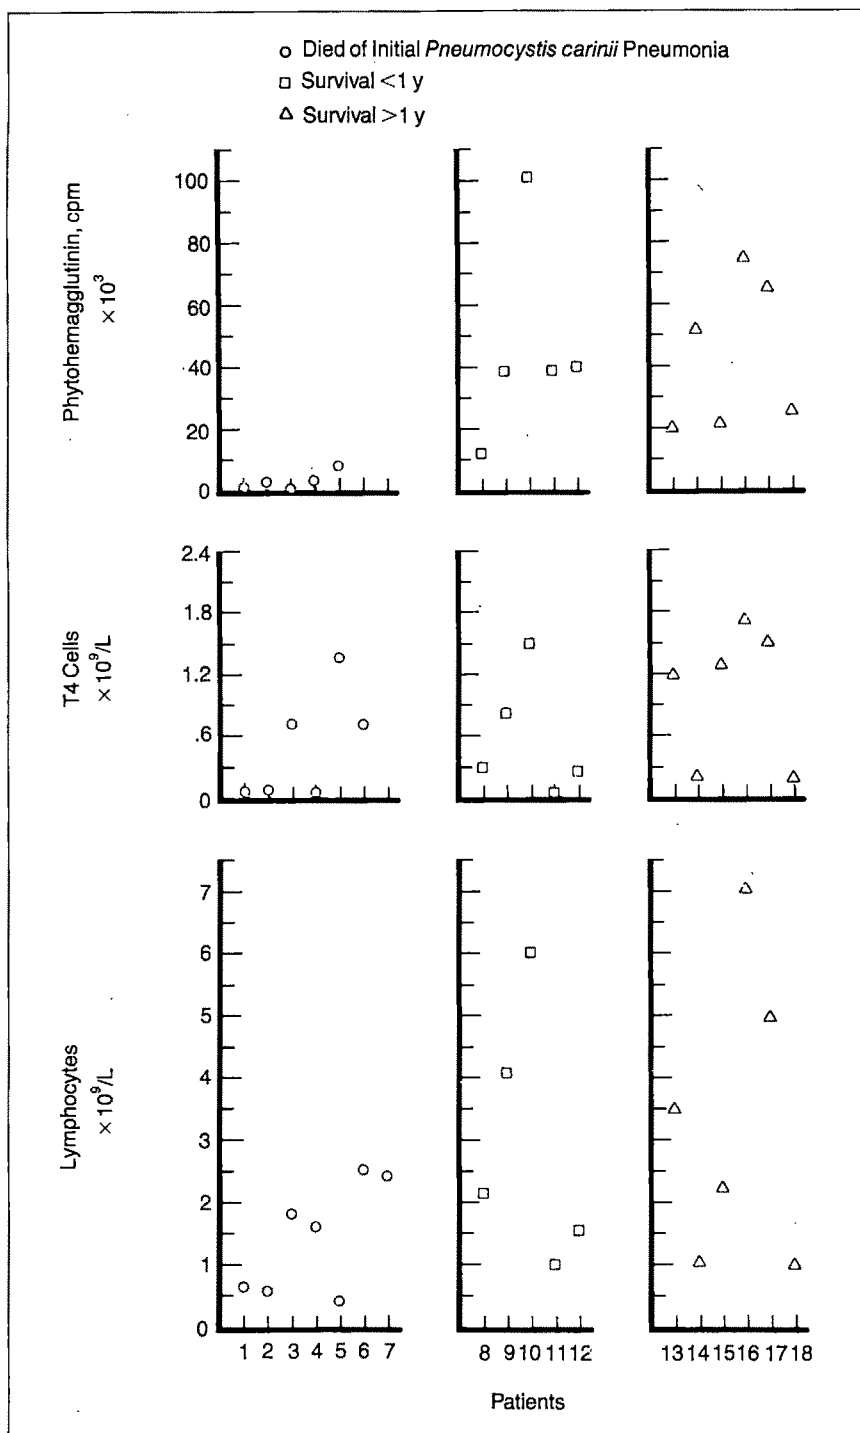

Fig 2.—Phytohemagglutinin responses, lymphocyte counts, and T4 cell counts in children with human immunodeficiency virus infection presenting with *Pneumocystis carinii* pneumonia. Patients were grouped by length of survival. Phytohemagglutinin responses were not obtained in patients 6 and 7; T4 cell count was not obtained in patient 7.

higher in patients surviving the longest, there was considerable overlap. No patient who survived an initial PCP attack had a markedly diminished PHA response, while the nonsurvivors had markedly diminished PHA responses.

Thus, the PHA response seemed to correlate best with short-term recovery from acute PCP.

Normal PHA responses in our laboratory are usually greater than 15 000 to 20 000 cpm or at least 50 times back-

ground counts. We consider a PHA response under 10 000 cpm to be significantly diminished. Similarly, ConA responses are usually 50 times background counts, and staphylococcal Cowan A and PWM are 20 times background counts. ConA responses did not predict survival as well as PHA, and ConA and PWM responses are diminished in most HIV-infected children, being the first immune abnormalities often seen.¹⁴

There have been several studies correlating immune status and clinical course in patients with HIV infection.¹⁵⁻¹⁷ In general, these studies demonstrated a higher incidence of opportunistic infection and poor outcome in patients with a diminished number of T4 cells and decreased lymphoproliferative responses both to mitogens and antigens. *Pneumocystis carinii* occurs in children both in the presence and absence of a normal PHA response. It appears that PHA response has more value in predicting survival from PCP in children, and not in identifying an at-risk group per se. It is not surprising that the patients with the poorest immune responses had the worst prognosis. However, there was no other specific clinical or laboratory finding at presentation that correlated as well as PHA response with survival from initial PCP. Mitogenic responses are not always available in acute situations. In our experience, it takes 3 to 4 days to obtain results. However, it does identify an at-risk population for fulminant PCP and early death. Identifying such a population is important in evaluating any future protocols regarding efficacy of PCP treatment or prophylaxis regimens.

As noted, in contrast to the adult studies, we saw no correlation between lactate dehydrogenase levels and survival. Albumin levels were lower in general in our older children, and levels of albumin were not predictive of survival. As we do not perform biopsies on children after therapy, we could not compare our data with those of Brenner et al.¹⁰ In fact, we rarely perform open lung biopsies at this point and rely initially on bronchoalveolar lavage.¹⁸

We cannot comment on the relative benefit of pentamidine vs trimethoprim/sulfamethoxazole, as others have.^{7,19}

Our use of anti-PCP drug therapy was not randomized and therefore no statement regarding the relative efficacy of each drug could be made. In the absence of a history of sulfa sensitivity, we routinely started our patients on a regimen of trimethoprim/sulfamethoxazole. In addition, the decision to switch from one drug to another, and the definition of "drug failure," was not always arrived at in the same manner in these patients. Pentamidine therapy tended to be initiated when the patient's condition was viewed as deteriorating with trimethoprim/sulfamethoxazole therapy, and this was often a subjective and variable decision. It should be noted that we have seen a significant incidence of adverse reactions to trimethoprim/sulfamethoxazole. Six children developed toxicity. Four had dermatitis, and two had bone marrow depression. While we prefer to maintain patients with prophylaxis therapy after PCP, trimethoprim/sulfamethoxazole therapy obviously had limitations.

The coexistence of other infections is important. Two of the seven patients who died were known to have disseminated MAI before presenting with *Pneumocystis*. One additional child was found to have disseminated cytomegalovirus infection at postmortem examination.

In two other children, premortem blood cultures subsequently yielded MAI after death. In one of these latter two children, blood cultures obtained shortly before death also yielded *C albicans*. This child was hospitalized for several weeks with multiple central lines. Of the initial survivors, one child was diagnosed with cytomegalovirus retinitis 2 months later, and five others subsequently developed MAI several months later. We feel that diminished immune status correlates with a higher risk for presentation with multiple opportunistic infections as well as early death from PCP. While five of seven children dying of acute PCP had an additional opportunistic infection, in only two was this clinically apparent before death; it would not be used as a predictor for PCP survival.

Our one surviving patient is of obvious interest. None of his laboratory data separate him from the other children who survived the initial PCP infection. He did go on to develop pulmonary lymphoid hyperplasia, which was confirmed histologically 1 year after PCP infection. Pulmonary lymphoid hyperplasia is an entity involving hyperplasia of the bronchial-associated lymphoid tissue.^{3,20}

It is not clearly associated with any pathogen, although Epstein-Barr virus has been implicated. He is the only one of our patients with PCP who subsequently developed pulmonary lymphoid hyperplasia. He has done well while receiving trimethoprim/sulfamethoxazole prophylaxis therapy, although he has required steroid therapy for his pulmonary lymphoid hyperplasia.²¹ There were no sequelae to his course of corticosteroids.

CONCLUSION

Children with PCP have a high incidence of mortality (39%) with their first attack. The prognosis for patients who survive the initial attack is extremely poor, with an overall mortality of greater than 90%. Thus, this group of children with HIV-1 infection clearly might benefit from more aggressive therapy for HIV-1 infection with agents such as zidovudine when they become available. To prevent the occurrence and recurrence of PCP, the use of prophylactic therapy in these high-risk children also needs to be evaluated.

This study was supported in part by grant AI 20671 from the National Institutes of Health, Bethesda, Md.

Pyomyositis in a Child With Acquired Immunodeficiency Syndrome

Patient Report and Brief Review

Stephen A. Raphael, MD; Barbara J. Wolfson, MD; Paul Parker, MD;
Harold W. Lischner, MD; Eric N. Faerber, MD

• Although common in tropical regions, pyomyositis is rare in the continental United States. Fewer than 50 cases have been reported to date. It is characterized by suppurative of large muscle groups that can, if not quickly and appropriately treated, lead to sepsis and death. Diagnosis can be difficult secondary to the atypical appearance of the abscess process early on. Almost all cases have occurred in otherwise healthy people. The simultaneous occurrence of pyomyositis and immunodeficiency is rare. A recent report of a case in an adult with the acquired immunodeficiency syndrome (AIDS) is not, however, unexpected. We describe the first documented occurrence of pyomyositis in a child with AIDS. A brief review of the topic is included. Pyomyositis should be included in the list of unusual infections that can occur in children with AIDS.

(AJDC. 1989;143:779-781)

Pyomyositis (spontaneous bacterial myositis, tropical and nontropical myositis, and primary suppurative myositis) is a suppurative bacterial infection of skeletal muscle usually caused by *Staphylococcus aureus*.¹ First described more than 130 years ago,² it is very common in tropical regions but rare in temperate climates.³ Since 1971, fewer than 50 cases have been reported in the continental United States.⁴ A pre-

dominance of healthy young males is noted.^{1,5} The youngest described patient is a 3-week-old neonate.⁶ A recent report describing this illness in an adult with the acquired immunodeficiency syndrome (AIDS)⁴ prompted this brief review of the topic and the first reported case of pyomyositis in a child with AIDS.

PATIENT REPORT

The patient, a 3½-month-old black male infant, was well until age 1 month, when hepatosplenomegaly, jaundice, and thrush were noted. Results of anti-human immunodeficiency virus (HIV) antibody tests (enzyme immunoassay with confirmatory Western blot) were positive in both the patient and his mother. The mother denied parental substance abuse and a history of blood product transfusion. She was, however, the sexual partner of an intravenous drug abuser who tested positive for anti-HIV antibodies. Additionally, the patient's serum was positive for HIV p24 antigen (Abbott Laboratories, North Chicago, Ill). The hepatosplenomegaly and jaundice were thought to be secondary to HIV infection. He was discharged with a diagnosis of perinatally acquired symptomatic HIV infection (AIDS).

Persistent fever and diarrhea developed. At age 3 months he was readmitted to the hospital. A swelling on the back had been noted 5 to 7 days prior to hospitalization. The physical examination revealed a small, undernourished, sickly appearing male infant in no acute distress. His height and weight were below the third percentile and his temperature was 37.6°C (axillary). Both heart and respiratory rates were increased (152 beats per minute and 42 breaths per minute, respectively). A small abscess was noted on the left eyelid. The tympanic membranes, heart, and lung were normal. Generalized lymphadenopathy was present. Liver and spleen enlargement and thrush were again

documented. A *Candida*-like rash involved the perineum. Neurologic examination results were abnormal. It was questionable whether the patient could follow light and respond to loud noises. Spontaneous nystagmus of the left eye was noted.

A 3 × 2-cm paraspinal mass lesion was found on the lower back to the left of the midline. The overlying skin was neither inflamed nor warm. There was no evidence of dermal suppuration. The lesion was firm, nontender, and barely noticeable while the patient was at rest; it became quite prominent, however, during crying or straining.

Results of laboratory studies showed an elevated total white blood cell count of $14.7 \times 10^9/L$ with 0.55 polymorphonuclear cells, 0.23 band forms, 0.17 lymphocytes, 0.03 mononuclear cells, 0.01 myelocytes, and 0.01 metamyelocytes. Marked anemia was present (hemoglobin, 79 g/L; hematocrit, 0.24). Lumbar puncture revealed $18 \times 10^6/L$ white blood cells and $1800 \times 10^6/L$ red blood cells. There were 0.51 polymorphonuclear cells, 0.37 lymphocytes, 0.10 band forms, and 0.02 mononuclear cells. Protein and sugar levels were normal. Gram's stain was negative. Moderate elevation of liver enzyme levels was noted: γ -glutamyl transferase, 230 U/L; alanine aminotransferase, 384 U/L; and lactate dehydrogenase, 1296 U/L. A chest roentgenogram showed an enlarged heart, interstitial infiltrates, and a small pleural effusion. The patient began to experience fevers to 39°C. Several physicians felt that the lack of erythema and warmth suggested the lesion was probably not an abscess. Nonetheless, intravenous antibiotic therapy (ceftriaxone) was initiated.

An ultrasound examination revealed a nonpulsatile paraspinal mass that was not cystic, did not contain fluid and/or air, and did not communicate with the spinal canal or retroperitoneum. The mass was deep to the fascia and when it was incised, yellow, nonfoul smelling, thick, purulent material was obtained. Loculated areas were disrupted

Reprints not available.

and the wound was irrigated and packed. Fifty milliliters of pus was evacuated. Gram's stain revealed very few gram-positive cocci in clusters.

Cultures of the abscess yielded penicillin-resistant *S aureus*. Ceftriaxone therapy was discontinued and intravenous sodium nafcillin therapy initiated. All other cultures, including blood, remained negative. The patient remained irritable and fed poorly. On the eighth hospital day, oral antibiotic therapy (cephalexin) was started. He was sent home several days later.

Two days after discharge, he was readmitted to the hospital. Elevated fibrin split products, low platelet count, and prolonged partial thromboplastin and prothrombin times were found. These findings were thought to be compatible with either disseminated intravascular coagulation and/or liver dysfunction, possibly secondary to hepatitis caused by HIV infection. The total white blood cell count on admission was $13.0 \times 10^9/L$ with 0.54 polymorphonuclear cells, 0.11 band forms, 0.34 lymphocytes, and 0.01 mononuclear cells. The patient had an acute pulmonary hemorrhage and died shortly thereafter. Permission for autopsy was denied. Cultures of blood, spinal fluid, and abscess cavity, taken on admission and prior to parenteral antibiotic therapy, yielded no organisms.

COMMENT

As stated above, pyomyositis is rare in the continental United States but is almost endemic in tropical regions. In Uganda, for example, it has accounted for almost 4% of all admissions to the surgical service of a large city hospital.⁷ Interestingly, many of the cases in the United States occur in areas that are characterized by high temperature and humidity.^{8,9} Clinically, there are no major differences between tropical and nontropical forms.

Many theories have been proposed to explain the discordance of geographic incidence and why muscle tissue, which is normally resistant to infection,⁹ can be affected in so isolated a way. These theories include (1) the possibility of concomitant parasitic¹⁰ or viral^{11,12} muscle infestation, which could lead to muscle fiber destruction and subsequent secondary bacterial infection; (2) nutritional imbalances^{13,14} leading to diminished host immune responsiveness; and (3) the role of preceding trauma to muscle tissue.¹⁵

The first two have not conclusively been shown to play a role, but there is evidence, from both laboratory animal²

and human clinical studies,¹⁶⁻¹⁸ that suggests that preceding trauma or interruption of vascular supply to muscle may be predisposing factors. The occurrence of a large number of cases in well-nourished and healthy citizens of the Hawaiian islands¹⁹ appears to diminish the role of poor nutrition and parasitic infestation as contributing factors. However, as study of the same series of patients suggests, preceding trauma and the occurrence of a concurrent and/or recent source of pyoderma may be significant. Perhaps transient bacteremia is also important, which might help explain the inability to document blood-borne infection in the vast majority of patients.³

A possible explanation for the tropical occurrence of this disease may be that people in these regions frequently walk shoeless and have a high incidence of repetitive minor foot trauma that may serve as loci for areas of "silent pyoderma"²⁰ that can lead to hematogenous spread.

A single muscle group is usually affected, but there may be multiple sites of involvement. The muscle groups most frequently involved include those of the thigh, buttocks, arm, lower leg, groin, chest wall, and shoulder, in decreasing order of frequency.¹ Approximately one third of patients have axial involvement.¹⁷

There are three stages of clinical progression.¹ The first is characterized by cramping pain and tenderness. Fever is not usually present. The illness progresses over 1 or 2 weeks with increasing edema, tenderness, and onset of fever. There may be a mild leukocytosis. The involved area feels indurated and has a "woody" quality. There is usually no evidence of fluctuance. As the untreated disease progresses into the second or suppurative stage, pain, tenderness, and edema intensify. Fever becomes prominent. Fluctuance occurs. Most patients seek treatment during this stage. The third stage is characterized by intense suppuration. The entire muscle may be replaced by pus. Septicemia and death may follow.

Diagnosis can be difficult. The disease may be mistaken for a variety of conditions, including muscle strain, hematoma, contusion, and soft-tissue sarcoma.²¹ This frequently occurs in the

early stages when there is little inflammation. Subsequent delay in therapy can be catastrophic. Muscle enzyme levels are rarely helpful in making the diagnosis.¹⁰

Localization of the purulent process has been aided by ultrasound,²² gallium scanning,²³ technetium Tc 99m bone scanning,²⁴ and computed tomography.²⁵ Technetium Tc 99m bone scanning is especially useful for detection of secondary silent sites.²⁶ Scanning techniques are also useful to rule out other conditions (such as vascular masses) that should be defined prior to surgery and to determine whether contiguous sites, such as bone, are involved.

The most commonly recovered organism, *S aureus*,³ is responsible for over 95% of cases. Most isolated organisms have been resistant to penicillin. The few cases caused by group A β -hemolytic streptococci appear to be more malignant and progressive.^{27,28} Recently, a case of toxic shock syndrome in association with pyomyositis has been described.²⁹

Therapy is relatively uncomplicated.¹ In the early stages, before large amounts of pus accumulate, many cases can be treated with intensive antibiotic therapy alone and will usually resolve in 2 to 3 weeks. For those who have entered the second stage of illness, surgical incision and drainage, in addition to antibiotic therapy (preferably a β -lactamase-resistant antistaphylococcal agent), is mandatory. If therapy is initiated quickly, complete resolution is the rule.

Our patient seems to have had a classic case of pyomyositis, which appears to have been diagnosed in the first stage of illness. A possible locus of infection was identified early (eyelid abscess). Unfortunately, this was not cultured. As noted, there was some question as to the nature of the mass. The classic occurrence of induration without redness or warmth, as is classically seen in pyomyositis, delayed the awareness that this was an abscess. If elevated, muscle enzyme levels might have suggested a diagnosis of myositis, but, as stated, results are almost always normal in patients with pyomyositis.

It is not surprising that this disease can be found in patients with evidence of immunodeficiency.⁴ Its occurrence in a

patient with transient hypogammaglobulinemia is documented.³⁰ Indeed, patients with pyomyositis have been described who have associated illnesses (diabetes mellitus,³¹ acute lymphocytic leukemia,³² Felty's syndrome,³³ and aplastic anemia³⁴) that can have immunodeficiency as part of their pathophysiology.

We cannot be sure that the death of this patient was not related to systemic bacterial infection. It would not be unexpected, however, that sepsis secondary to pyomyositis could be a cause of serious illness in young children with AIDS. The immunodeficiencies in these children^{35,36} make them particularly susceptible to infection with virulent pyogenic organisms.³⁷ The possible usefulness of prophylactic intravenous immunoglobulin therapy for bacterial infection in these patients comes to mind when presented with a case like this. Although the efficacy of such therapy is not definitively known, this child was being considered for entry into the national placebo-controlled double-blind study of such therapy.

Pyomyositis should be added to the list of those infrequent, but not necessarily opportunistic, bacterial infections that can cause increased morbidity and mortality in children with AIDS.

Mucopolysaccharidosis I Presenting With Endocardial Fibroelastosis of Infancy

Mark J. Stephan, MD; CPT Edward L. Stevens, Jr, MC, USA; Richard J. Wenstrup, MD; Cheryl R. Greenberg, MD; Hilda L. Gritter, MD; CPT George F. Hodges, MC, USA; LTC Barbara Guller, MC, USA

• We describe two female infants with Hurler syndrome (mucopolysaccharidosis I) whose deaths are attributed to cardiac failure with associated, autopsy-confirmed endocardial fibroelastosis. One infant had confirmed α -L-iduronidase deficiency in cultured dermal fibroblasts, and the other infant had histologic evidence of tissue mucopolysaccharide accumulation at autopsy and a sibling with confirmed α -L-iduronidase deficiency and the Hurler syndrome phenotype. Clear cells ("Hurler" cells) were identified within the myocardium and endocardium of both infants. We propose that the ventricular mural accumulation of mucopolysaccharides induced extensive proliferation of elastic or collagen fibers within the endocardium. Cardiac failure may precede recognition of clinical and roentgenographic features of Hurler syndrome. Our findings and a literature review suggest that certain heritable storage disorders, including mucopolysaccharidosis I, should be considered when infants have clinical electrocardiographic and echocardiographic findings consistent with endocardial fibroelastosis or have autopsy-documented endocardial fibroelastosis.

(AJDC. 1989;143:782-784)

Endocardial fibroelastosis of infancy (EFE), characterized by a thickened noncompliant left ventricle, can be present or develop in a causally heterogeneous group of cardiac disorders. Previously, EFE has been pathogenetically attributed to viral infections, hereditary and nonhereditary congenital de-

velopmental defects in the endocardium, subendocardial hypoxia, and impaired lymphatic drainage of the heart.¹ Lurie² recently emphasized the concept of EFE as a reactive process set off in the endocardium by a stressed myocardium, as a result of a viral inflammatory process, obstructive defect of the left heart, genetic disorder, etc. We describe two infants with congestive heart failure and EFE as a presenting manifestation of mucopolysaccharidosis I (MPS I [Hurler syndrome]).

PATIENT REPORTS

PATIENT 1.—A female infant was the product of an uncomplicated term pregnancy and delivery to 26-year-old, nonconsanguineous white parents. Her birth weight was 3.5 kg; length, 49.5 cm; and head circumference, 33 cm. The family history was negative for birth defects, known heritable disorders, mental retardation, and heart disease of childhood onset. Growth and development during early infancy were normal. At age 4 months she was hospitalized with a 2-week history of poor feeding, increased sweating, and labored breathing. Physical examination revealed a head circumference of 42.3 cm (90%), slight frontal bossing, synophrys, and a high-arched palate. Her respiratory rate was 48/min without subcostal retractions or adventitious sounds. The heart rate was 180 beats per minute, and the point of maximal cardiac impulse was displaced to the left anterior axillary line. No cardiac murmur was auscultated. The liver was palpable 4 cm below the right costal margin with a span of 7 cm by percussion. The spleen tip was palpable at the level of the umbilicus. No extremity edema or limitation of joint mobility was present. Neuromuscular tone and deep tendon reflexes were normal.

Chest roentgenograms confirmed marked cardiomegaly. An electrocardiogram was significant for ST segment depression in leads II, III, and aVF and left-ventricular hypertrophy with strain as well as poor R-wave progression from the right to the mid-precordial leads. An echocardiogram was remarkable for severely reduced left-ventricular contractility and thickening of the left-ventricular wall and septum compatible with a cardiomyopathy. The mitral valve was also thickened. Viral cultures of the

throat and rectum were negative. Acute and convalescent serum complement fixation titers for enteroviruses, including coxsackievirus B, were negative. The patient was given oxygen, digitalis, and diuretics, resulting in marked clinical improvement.

Because of mild facial coarsening and marked splenomegaly, the diagnosis of a metabolic storage disease was entertained. Peripheral blood smear examination revealed numerous vacuoles in the cytoplasm of lymphocytes. Roentgenograms demonstrated anterior hypoplasia and beaking at L-2 and L-3, and slightly broadened phalanges. Slit-lamp examination confirmed mild corneal clouding bilaterally. Results of a urine mucopolysaccharide screen were positive for dermatan sulfate and heparan sulfate. Electron microscopy of skin revealed the presence of storage material. A skin fibroblast assay confirmed the absence of α -L-iduronidase activity compatible with MPS I.

By age 6 months the patient had mild hypotonia and mild thoracolumbar kyphosis. Her motor developmental index was 92 and her performance developmental index was 86 on the Bayley Scales of Infant Development.

At age 9 months the patient died of severe congestive heart failure precipitated by an upper respiratory tract infection.

At autopsy the most striking findings were noted in the heart, which was markedly enlarged at 95 g (normal, 41 ± 5 g), with a diffusely pale, glistening appearance. The mural endocardium of all chambers was diffusely thickened up to 0.1 cm, most prominently within the left ventricle, and especially the membranous portion of the ventricular septum and chordae tendinae. There was thickening of the mitral and aortic valve leaflets without evidence of stenosis. Severe luminal narrowing up to 70% was present focally within all three major coronary arteries. Histologically, the myocardium showed mild hypertrophy, with numerous collections of clear ("Hurler") cells in the interstitium between myocardial fibers. These clear cells stained with alcian blue (pH 2.5), periodic acid-Schiff, and toluidine blue. The endocardial and epicardial thickenings were composed of proliferations of fibroelastic tissue, confirmed by elastic stains. Few clear cells could be demonstrated by special stains within the fibroelastic proliferations, and they were noted predominantly adjacent to the myocardium. The coronary artery narrowing and the valvular thickenings were due to

accumulations of clear cells and collagen.

Other autopsy findings included hepatomegaly (410 g; normal, 288 ± 67 g) and splenomegaly (41 g; normal, 18 ± 5 g). Varying numbers of clear cells were identified with special stains in most organs, most prominently in the liver sinusoids, renal interstitium, thymus, lungs, and lymph nodes. There was prominent vacuolization of hepatocytes. Permission for postmortem examination of the central nervous system was denied.

PATIENT 2.—The first girl born to a non-consanguineous, healthy couple was the product of a term, uncomplicated pregnancy and delivery. Her birth weight was 3.8 kg and her birth length was 51 cm. An incomplete cleft of the hard palate and left talipes equinovarus were present. She was an irritable infant who had recurrent upper respiratory tract infections. At age 5 months her motor development was mildly delayed. At age 8 months her head circumference was 46 cm (>95%), with a large anterior fontanelle measuring 4×5 cm. A respiratory illness developed at age 8 months, and she was subsequently found dead in her crib. A postmortem examination established the presence of EFE.

The family's second daughter was physically and developmentally normal. The third daughter was referred at age 1 year for genetic evaluation because of global developmental retardation. She was the product of an uncomplicated term pregnancy, her birth weight was 3.7 kg, and her length was 51 cm. The parents noted a striking resemblance in the child's early infancy to their first child, who had died of EFE. Physical examination at age 12 months revealed a flat nasal root, facial coarsening, bilateral corneal clouding, and hepatosplenomegaly. Results of cardiac examination were normal.

Roentgenograms revealed inferior beaking of L-2 and L-3 anteriorly and broadened metacarpals and phalanges. Urine mucopolysaccharide excretion was elevated at 90 cetyl pyridinium chloride units per millimole of creatinine by the alcian blue method. A white blood cell α -L-iduronidase assay revealed an almost complete deficiency (0.007 U per gram of protein). Her most recent evaluation at age 4 years revealed a typical Hurler syndrome phenotype, with short stature (94 cm). Echocardiography revealed thickening of the aortic and mitral valves, but endocardial thickening was not noted.

Review of the autopsy of the first sibling was significant for marked cardiomegaly (89.6 g). The left ventricle was globular, and there was marked dilatation of the left ventricle, right atrium, and right ventricle, with mild left-atrial dilatation. The salient feature on gross pathologic examination was striking pallor of the thickened endocardium of the left ventricle and right ventricle, most pronounced near the base of the aortic valves

and the base of the pulmonary valves, respectively. Microscopically, the endocardial thickening consisted primarily of collagenous fibers and reticular tissue. There was no significant elastic tissue with special stains. The endocardium stained mildly metachromatic with toluidine blue and showed scattered cells with fine vacuolization of enlarged cytoplasm. The myocardial cells showed no vacuolization, but there was some separation of myocardial fibers by clear cells in the interstitium adjacent to the endocardium. The aortic cusps were slightly thickened, and there was fine pebbling of the endothelial lining of the ascending aorta. There was marked intimal thickening of the coronary arteries, with 60% stenosis, consisting largely of fibrous tissue and clear cells, with destruction of the internal elastic lamina.

Other autopsy findings included hepatomegaly (310 g; normal, 277 g) with fine vacuolar changes in the parenchymal cytoplasm and periodic acid-Schiff-positive material that was present primarily in the Kupffer cells, splenomegaly (32 g; normal, 20 to 25 g), flocculent material in Bowman's space in the kidneys, and pulmonary edema with a few areas of focal alveolar collapse. Sections of the spleen and central nervous system were not available. The brain was enlarged (935 g; normal, 714 to 852 g). Bacterial cultures of the blood, cerebrospinal fluid, and both lungs were negative. *Klebsiella pneumoniae* grew from a tracheal culture. Viral cultures of the heart and right lung were negative.

COMMENT

These two female infants with EFE were affected by an underlying mucopolysaccharide storage disorder, MPS I. Although the diagnosis was biochemically proved only in patient 1, the phenotype of patient 2, the characteristic pathologic changes, and biochemically proved MPS I in a full sibling almost certainly make this the primary diagnosis in patient 2 as well.

Although past epidemiologic data for EFE indicated an incidence of 1 in 5000 to 6000 live births,³ its incidence in North America has decreased in recent years.⁴ Its clinical presentation features the rapid onset of low-output cardiac failure in early infancy, often precipitated by an upper respiratory tract infection. Neither the clinical^{1,5} nor echocardiographic^{1,6} findings of EFE are pathognomonic, and its presence is confirmed by endomyocardial biopsy procedure or at autopsy. Microscopically, the fundamental pathologic change is the thickened endocardium, composed principally of elastic and collagenous fibers.⁷

Endocardial fibroelastosis is causally

heterogeneous; its etiologic and pathogenetic considerations and natural history have been extensively reviewed.^{2,5,8,9} Serologic and cultural evidence of extrauterine or intrauterine viral infection has strongly implicated coxsackievirus B myocarditis^{1,10-12} and, less commonly, other viruses.

Although most cases of EFE occur sporadically, familial occurrence of EFE has been documented, including parental consanguinity^{13,14} and concordance in monozygotic twins.¹⁵⁻¹⁷ Various patterns of inheritance have been proposed for familial cases, including autosomal recessive,¹⁸⁻²⁰ X-linked recessive,^{21,22} and incompletely penetrant autosomal dominant.^{22,23} The reported familial incidence of EFE in siblings has ranged from 4.0% to 19.0%.^{22,24,25} After reviewing the family studies of Chen et al,²⁴ Opitz⁸ suggested that, once cases presumed to have been induced by viruses are discounted, the empiric recurrence risk for the remaining cases may approach the 25% segregation ratio expected for an autosomal recessive trait.

This familial occurrence of EFE suggests the possibility of a genetically transmitted abnormality affecting myocardial metabolism. Glycogen storage disease type IIa and associated EFE have been previously reported in siblings,^{26,27} with biochemical and autopsy confirmation of their association.²⁷ In any case of EFE or familial cardiomyopathy, treatable entities, such as systemic carnitine deficiency, must be sought.²⁸⁻³⁰ Autopsy-confirmed EFE has been reported in two infants with Niemann-Pick disease type A^{31,32} and in GM-2 gangliosidosis (Sandhoff disease).³³ Neustein et al³⁴ reported severe biventricular EFE and abnormal mitochondria with X-linked recessive inheritance.

In view of the sudden early onset of cardiac failure of the patients described in this report, we propose that MPS I should be considered among the differential causes of EFE of infancy. Two previously described 4½-month-old infants who were facially normal and who died with clinical manifestations associated with EFE had autopsy findings of enlarged vacuolated cells in the heart, liver, lymphatic tissue, and spleen, which are compatible with MPS.^{35,36} The infant described by Strauss and Platt³⁵ had a thickened endocardium consisting of abundant elastic and collagenous fi-

bers, between which were embedded vacuolated cells. These pathologic findings are present in patient 1 in the present report. The endocardium of the infant described by Lindsay³⁶ was thickened, with abundant swollen vacuolated collagenous fibers; this is histologically similar to our review of the pathologic findings of patient 2 in the present report. Fong et al³⁷ reported EFE in infant siblings with MPS VI (Maroteaux-Lamy) who presented with cardiac failure.

Mucopolysaccharidosis I is due to a genetic deficiency of α -L-iduronidase, a specific lysosomal hydrolase responsible for the normal degradation of acid mucopolysaccharides. Intracellular accumulation of acid mucopolysaccharides and glycolipids develop in various tissues, and patients have excessive urinary excretion of dermatan and heparan sulfates. Dermatan sulfate normally plays a role in the extracellular organization of collagen, and an excess of dermatan sulfate in MPS I may induce abnormally extensive collagen deposition at inappropriate sites.³⁸ The cardiovascular pathologic findings of MPS I³⁹ are characterized by accumulation of clear cells, granular cells, and collagen bundles, with resultant diffuse thickening of various regions of the cardiac substructure, including the valve leaflets and annuli, chordae tendinae, and the membranous portions of the ventricular septum, endocardium, epicardium, and coronary artery intima. Hypertrophy of the myocardium, with clear cells present in the interstitium, and focal infiltration of the sinoatrial and atrioventricular nodes by fibroelastic tissue may also occur. We propose that mucopolysaccharide deposition was responsible for myocardial malfunction and stress, with the proliferation of collagen and/or elastic fibers within the endocardium of the hearts of these two infants, contributing to their sudden decline of cardiac function. Increased ventricular wall tension secondary to acid mucopolysaccharide accumulation within the myocardium may contribute to the process of endocardial thickening. Renteria et al³⁹ noted thickening of the mural endocardium from proliferation of elastic and collagenous fibrils in necropsy studies of five older children with MPS I. Some degree of endocardial fibroelastosis was noted as an incidental finding in various forms of MPS in one fifth of 68

autopsies that included cardiovascular pathologic examination.⁴⁰

We do not know how frequently MPS I initially clinically presents with low-output cardiac failure during infancy rather than the more widely recognizable facial coarsening, skeletal changes, corneal clouding, and developmental delay. However, the evaluation of even an isolated case with clinical and/or autopsy findings compatible with EFE during infancy warrants consideration of a growing list of metabolic disorders. These include MPS I and VI, carnitine deficiency, glycogen storage disease type II, Niemann-Pick disease, Sandhoff disease, and, potentially, others.

We thank Martha San Nicolas, Sarah Overaker, and Teresa Bryant for secretarial assistance.

Beware of Overtreating Children!

Allan S. Cunningham, MD

Some years ago I witnessed a clinical catastrophe involving a 4-year-old boy. A history of headaches led to skull roentgenograms that disclosed a large pituitary fossa. This triggered a series of clinical decisions that were climaxed by a carotid hemorrhage during transphenoid biopsy. Autopsy revealed an empty sella and a benign lymphangioma in adjacent bone. The case was a source of fascination and much earnest and perplexed discussion. The consultants had little experience with similar cases and it was not entirely clear who was in charge. The cause of the headaches in this otherwise-normal boy was never known, and the long-range outlook without intervention was strictly speculative. However, it was an avoidable catastrophe and the case sensitized me to the factors that cause overtreatment of children. Four recent journal articles have crystallized some random thoughts about this problem.

1. Stickler¹ discussed two infants who underwent unnecessary surgery that completed a chain of clinical decisions beginning with the naive use of growth charts.

2. The *British Medical Journal*² summarized the terrible repercussions of an epidemic of false sexual abuse that resulted when two inexperienced physicians overinterpreted a single physical sign known as reflex anal dilatation.

3. Sepkowitz³ chronicled the stagger-

ing increase in the rate of newborn intubation at one community hospital following the publication of unsupported guidelines for the management of meconium staining.

4. Kemper⁴ documented the large number of children hospitalized unnecessarily.

These articles will strike a chord in pediatricians who have broad experience, and they need to be read in detail. For our purposes the articles serve as a suitable introduction to the subject of overtreatment in children.

THE CASCADE EFFECT

There is a natural medical bias for "doing," and medical educators place great emphasis on early diagnosis and treatment. This emphasis is proper, but few experienced clinicians would deny that it has unwholesome side effects that produce a professional attitude toward patients that is a blend of altruism and fear. It leads to what one observer has called a "solemn commitment to the principle that the patient is sick until proved well,"⁵ and it has caused much mischief by way of frivolous testing, treatment, consulting, and hospitalization. The mischief occurs because, once begun, the investigative process is hard to stop, a reality that has been dubbed "the cascade effect."⁶

The term *cascade* refers to a process that proceeds stepwise but inevitably to its conclusion. The coagulation cascade and the complement cascade are familiar examples, but the effect occurs in larger biological systems such as the decision-making processes of medical groups. The momentum of the cascade effect in clinical decisions is the result of

several factors that is aptly summarized by *DICE*, a recently coined acronym.⁷

D stands for "diffusion of responsibility." The physician's sense of responsibility for therapeutic catastrophe declines in proportion to the number of consultants on a case. It can occur in any medical environment. Schoolman⁸ observed that clinical decision making in teaching hospitals

evolves through a series of subspecialists who provide an environment in which the diffusion of responsibility for decision making is tolerated, if not promoted. This environment permits the physician to deal with his discomfort by an acceptable procedure of allowing decisions to be made by others. When this procedure assumes multiple dimensions, the result is that no one is responsible for the patient. Decisions are made not by a patient advocate, but rather by a therapeutic advocate.

Balint⁹ has termed this phenomenon "the collusion of anonymity." In the boy whose case I used as my first example, seven different medical and surgical specialists had been consulted and it was not clear who was directing his care. Sometimes responsibility is surrendered to outside experts whose "guidelines" are used to make clinical decisions. The effect of guidelines or "standards of practice" is not always salutary, as emphasized in Sepkowitz's report.

I stands for "inexperience." We are more likely to initiate a clinical cascade with tests or procedures that we trust, and we tend to be more trusting at the beginning of our professional careers. Moreover, as experience increases clinicians tolerate wider deviations from normal in their patients and are less

Accepted for publication February 20, 1989.

likely to initiate an unnecessary search for a pathologic lesion. Experience relates to persons, problems, and procedures. How well does the physician know the child? Is this the first clinical encounter? If the physician is a consultant, has he or she talked to the parents himself or herself, or has the history been obtained at face value from the patient's medical record? How many times before has the physician seen similar clinical problems? For an established diagnosis, is there a grasp of the condition's natural history? Is the clinician's general experience broad enough to recognize that the problem is outside his or her narrow expertise? If a procedure is involved, has he or she performed it before? For diagnostic procedures, is the technology standardized well enough to establish the range of normal or the effects of age? These questions are not merely rhetorical, and they apply to attending physicians as well as trainees. The physician primarily responsible for the false epidemic of sexual abuse had been in practice for less than 1 year,² and the decisions to operate on Stickler's^{1,10} patients rested heavily on data obtained from a poorly standardized procedure.

C stands for "cookbook thinking." Its first element is a tendency to make artificially sharp distinctions between normal and abnormal. Thus, the infant at the fifth percentile is considered sickly, simply because he is 2 SDs below the mean for height or weight, thereby initiating the cascade observed by Stickler.¹ A second element is the tendency to assume that all deviations from normal are related and to confuse simple association with causality. Thus, Sepkowitz⁸ report reveals that meconium is believed to be a cause of respiratory distress rather than a marker. This leads to a second error, which is a tendency to overlook the risks of intubation.^{11,12} The erroneous diagnosis of sexual abuse resulted from inadequate knowledge of the normal anus. The result was a social catastrophe.² Cookbooks are useful and they are necessary, particularly in bona fide emergencies. But recipes have subtleties that cannot be written down. The best cooks—and the best physicians—appreciate this.

E stands for "economics." Professional competition is intense. When incen-

tives are offered for performing tests or administering treatments regardless of outcome, and when status is increased by filling hospital beds, clinical perceptions change and there is an additional impulse toward treatment. This is particularly true when the physician's sense of personal responsibility is blunted and when he or she is insecure. By validating or invalidating certain clinical practices, good research can retard this impulse, although the economic incentives are sometimes too strong to permit valid trials. One doubts that economic incentives in the preceding cases were strong or direct, but they do not have to be.

Physicians today are accused of being "too scientific." It is one way patients have of complaining about impersonal care. But the criticism is misplaced. It is not science but technology that is the likely culprit. It is science—in the best sense—that will improve the *personal* quality of care by allowing us to choose truly helpful technology, use it appropriately, and discard what is useless or harmful.¹³

There is one other contributor to the cascade effect. This is *curiosity* or the *craving for certainty*.¹⁴ The fact that we cannot explain many of our patients' symptoms is a frustrating reality, and technology offers a kind of release in the form of a number, a tracing, or an image. Unfortunately, it also leads to artificial inflation in the amount of pathologic disorder harbored by a given population. Adolescents with chest pain or palpitations, for example, would be wise to keep quiet nowadays lest they initiate a series of examinations culminating in a diagnosis of "mitral valve prolapse." This is what the echocardiogram now finds in 35% of normal adolescents!¹⁵ The craving for certainty may have more sinister results if it leads to unnecessary lymph node biopsy and the erroneous diagnosis of malignancy.¹⁶ I do not suggest that chest pain or swollen glands be ignored. But the vast majority of these symptoms, and a host of other complaints, are self-limited. They teach us to exercise considerable restraint before we scratch the diagnostic itch.

We should acknowledge that disastrous and unnecessary clinical cascades are sometimes initiated by parents. Cir-

cumcision is a homely example. Routine circumcision of newborns is no longer recommended by most physicians and is done only if parents request it. Catastrophes are rare, but they do occur.¹⁷ Overuse of antibiotics is, in part, the result of parental pressure, with some regrettable results.¹⁸ I have seen parental cancer phobia and craving for certainty lead to unnecessary node biopsies and serious complications. Clinicians, of course, share responsibility for these misadventures, but the role of parental pressure in initiating an unfortunate chain of clinical events should not be ignored. Knowledge of the cascade effect and its trigger factors should help clinicians to resist such pressure.

THREE GOOD PHYSICIANS

There is another antidote to diagnostic and therapeutic excess. It is the patient who surprises us by recovering from serious illness (or what we thought was serious illness) with little or no treatment. Until we see such patients ourselves, we can learn from clinicians who have. I know of three outstanding examples.

Robert Bolande, MD, was the pediatric pathologist at my alma mater. His was a name I learned to recognize when I scanned the journals. In 1969 he published the report of an infant who recovered from disseminated neuroblastoma with no treatment whatsoever,¹⁹ and he wrote a series of articles pressing the point that malignant neoplasms in childhood are not always what they seem.²⁰

Eugene Blank, MD, was the pediatric radiologist during my residency. He had first been a pediatrician, and I remember his sympathy for sick children, as well as his warnings to the residents against overinterpreting "shadows on x-ray film." It was the heyday of aggressive pediatric urologic surgery, but he taught that reflux was largely a developmental phenomenon²¹ and that antireflux surgery was of dubious value. He was right²² and the lessons he taught carried over to other clinical areas, so that we learned to approach "abnormal" test results with skepticism and deliberation.

Ronald Illingworth, MD, has had a long and distinguished career in British pediatrics. He teaches that the first principle of pediatrics is "know the nor-

mal, or else . . ." and that its first corollary is the extraordinary range and variety in observations of healthy children.²³ His wide experience permitted a reserve of optimism, even for the most worrisome cases.²⁴

These clinicians and scholars, and others like them, remind us of the limits of medical knowledge and the virtues of patience and therapeutic restraint. Their observations are a tonic against clinical arrogance, anxiety, and haste.

COMMENT

We deal with elastic concepts and vague boundaries between normal and

abnormal, and it is too easy to allow nonclinical factors to intrude on clinical perceptions and decisions. In an era of marketing, competition, technological pressure, and overspecialization, physicians must remember they are primarily counselors, not technicians.²⁵ When consensus conferences assess clinical practices we must insist on honest science, not votes, as these practices legitimate support.²⁶ We are inundated by information and experts, but we cannot allow judgment to be warped by the craving for certainty. We need guidelines, but when "standards of practice" are legalistically imposed we must not

forget that it is individuals we care for and individuals who provide the care.

This is not a counsel of despair. Experienced clinicians can be found to solve most problems, and professional cooperation need not lead to diffused responsibility. Cookbook thinking is overcome by education and experience, and unwholesome economic factors are overcome by an altruistic spirit. I recognize that overtreatment is not the only problem in the medical care of children. However, in the present professional climate, I believe it is a serious problem that deserves emphasis and our attention.

PediOtic[®] suspension sterile

Formulated to be less acidic
to help minimize irritation.

A more normal pH range means less potential for painful irritation.

Formulated to help take the sting out of otitis externa therapy

PediOtic suspension is specially formulated to have a higher pH range than conventional otics.

Children may be less likely to resist its instillation, and their parents will appreciate the ease of compliance.

And you can prescribe PediOtic suspension with confidence, knowing it

contains the same proven antibiotic/anti-inflammatory combination physicians have trusted for years.

Now there's a gentle effective treatment for "swimmer's ear" to please patient, parent, *and* physician.

Please see brief summary of prescribing information on next page.

PediOtic[®] suspension sterile

(polymyxin B sulfate-neomycin sulfate-hydrocortisone)

PediOtic[®] suspension sterile (polymyxin B sulfate-neomycin sulfate-hydrocortisone)

DESCRIPTION: PediOtic suspension (polymyxin B sulfate-neomycin sulfate-hydrocortisone) is a sterile antibacterial and anti-inflammatory suspension for otic use. Each ml contains: Aerosporin[®] (polymyxin B sulfate) 10,000 units, neomycin sulfate equivalent to 3.5 mg neomycin base, and hydrocortisone 10 mg (1%). The vehicle contains thimerosal 0.001% (added as a preservative) and the inactive ingredients cetyl alcohol, glyceryl monostearate, mineral oil, polyoxyl 40 stearate, propylene glycol, and Water for Injection. Sulfuric acid may be added to adjust pH. PediOtic suspension has a minimum pH of 4.1, which is less acidic than the minimum pH of 3.0 for Cortisporin[®] Otic Suspension.

INDICATIONS AND USAGE: For the treatment of superficial bacterial infections of the external auditory canal caused by organisms susceptible to the action of the antibiotics, and for the treatment of infections of mastoidectomy and fenestration cavities caused by organisms susceptible to the antibiotics.

CONTRAINDICATIONS: This product is contraindicated in those individuals who have shown hypersensitivity to any of its components, and in herpes simplex, vaccinia, and varicella infections.

WARNINGS: This product should be used with care in cases of perforated eardrum and in longstanding cases of chronic otitis media because of the possibility of ototoxicity. Neomycin sulfate may cause cutaneous sensitization. A precise incidence of hypersensitivity reactions (primarily skin rash) due to topical neomycin is not known. When using neomycin-containing products to control secondary infection in the chronic otitis media, such as chronic otitis externa or stasis dermatitis, it should be borne in mind that the skin in these conditions is more liable than is normal skin to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low-grade reddening with swelling, dry scaling and itching; it may be manifest simply as a failure to heal. Periodic examination for such signs is advisable, and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for the patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of non-susceptible organisms, including fungi.

If the infection is not improved after one week, cultures and susceptibility tests should be repeated to verify the identity of the organism and to determine whether therapy should be changed.

Treatment should not be continued for longer than ten days.

Allergic cross-reactions may occur which could prevent the use of any or all of the following antibiotics for the treatment of future infections: kanamycin, paromomycin, streptomycin, and possibly gentamicin.

ADVERSE REACTIONS: Neomycin occasionally causes skin sensitization. Ototoxicity and nephrotoxicity have also been reported (see WARNINGS section). Adverse reactions have occurred with topical use of antibiotic combinations including neomycin and polymyxin B. Exact incidence figures are not available since no denominator of treated patients is available. The reaction occurring most often is allergic sensitization. In one clinical study, using a 20% neomycin patch, neomycin-induced allergic skin reactions occurred in two of 2,175 (0.09%) individuals in the general population.¹ In another study, the incidence was found to be approximately 1%.²

The following local adverse reactions have been reported with topical corticosteroids, especially under occlusive dressings: burning, itching, irritation, dryness, folliculitis, hypertrichosis, acneiform eruptions, hypopigmentation, perioral dermatitis, allergic contact dermatitis, maceration of the skin, secondary infection, skin atrophy, striae, and miliaria. Stinging and burning have been reported rarely when this drug gained access to the middle ear.

HOW SUPPLIED: Bottle of 7.5 ml with sterilized dropper. NDC 0081-0910-02. Store at 15° to 25°C (59° to 77°F).

Urine Drug Screening in Mothers and Newborns

John D. Osterloh, MD, MS, Belle L. Lee, PharmD

• A retrospective analysis of comprehensive urine drug screening was performed during a 13-month period on specimens submitted from the Neonatal Nursery and Obstetrics/Gynecology wards at San Francisco (Calif) General Hospital (mothers, N=601; newborns, N=339). Of mothers and newborns, respectively, 19.2% and 15.3% of all admissions during this period were screened; 68.2% and 63.1% of urine samples submitted were positive for any drug; 38.8% and 21.1% of screens were positive for more than one drug; and 45.8% and 41.6% were positive for cocaine. In mother-newborn pairs (N=191) where urine samples were submitted within 4 days of each other, an 84% concordance was shown for cocaine and 67% for methadone, but concordance was much less for other drugs (<21%). These results indicate that cocaine was the most common drug detectable in the peripartum period and that both mothers and newborns should be tested to confirm the suspicion of drug effect or withdrawal in the newborn.

(AJDC. 1989;143:791-793)

The diagnosis of the effects of drug abuse on the newborn during the peripartum period depends on clinical signs and confirmation with urine drug testing in the newborn and mother. Though there is active investigation into the effects of drugs on the fetus and newborn,^{1,2} little is known about the types of drugs found in neonatal testing and about the concordance of drug detection in the mother and newborn. We conducted a retrospective survey of drug testing results from urine specimens submitted from obstetrics/gynecology and neonatal services in a large inner-city hospital to characterize the

types of drugs and concordance in mothers and newborns.

SUBJECTS AND METHODS

Urine drug screen results from the Neonatal Nursery and Obstetrics/Gynecology wards were compiled, covering a period of 13 months from April 1, 1987, through April 30, 1988. Drug screening was ordered by house staff for diagnostic purposes, to differentiate possible drug effect from signs caused by disease or pregnancy. Urine drug screens for mothers had been ordered on the basis of (1) a history of drug abuse, (2) signs and symptoms of drug use (track marks, skin abscesses, nasal mucosal ulceration), or (3) signs of pharmacologic effect (eg, elevated blood pressure due to cocaine vs pregnancy or disease). In the newborns, urine drug screens were ordered when there was (1) suspicion of drug effect (eg, opiate-induced respiratory depression or cocaine-induced irritability), (2) drug withdrawal (irritability, failure to feed, vascular instability, poor motor performance, wakefulness, tremulousness, hyperactivity, or hyperreflexia), or (3) a history of drug abuse or positive urine drug screen in the mother. Because specimens were submitted from both obstetric and gynecologic services, not all specimens were from mothers. The actual proportions of drug screens received from nonmother gynecologic patients is unknown. However, based on data after this study, the proportion appears to be less than 2%.

Urine samples were received by the San Francisco (Calif) Public Health Toxicology Laboratory at San Francisco General Hospital. Maternal urine samples were always screened by means of the following eight procedures: separate enzyme immunoassays for cocaine metabolite, opiates, and benzodiazepines (EMIT-Dau; Syva Company, Palo Alto, Calif); two chemical spot tests for salicylate and phenothiazines; thin-layer chromatography (Toxi-lab; Analytical Systems, Irvine, Calif) for 35 basic drugs including antidepressants, antihistamines, phenothiazines, narcotic analgesics, xanthines, amphetamines, and some sedatives; gas chromatography with flame ionization detection for alcohol; and gas chromatography with nitrogen-phosphorus detection, which will

detect or confirm a variety of drugs similar to that listed for thin-layer chromatography. In the newborns, the same procedures were applied except that the sensitivity of the gas chromatography procedure was severalfold less due to limited urine volume from the newborns (usually <10 mL). Approximately 80 different drugs of abuse and pharmaceuticals can be detected by these combined procedures. These methods allow detection of most drugs within 2 days of administration of recreational or therapeutic doses, except for alcohol, salicylate, and acetaminophen (detection interval, <1 day after dose).

The test results were compiled in two ways. Data from mothers and newborns were tabulated separately as to the number and types of drugs found. When a newborn urine specimen was received in the laboratory within 4 days of receiving the urine specimen from the mother, this was designated a mother-newborn pair. These were compiled as to types of drugs and agreement between findings in mothers and newborns.

RESULTS

A total of 940 urine drug screens were requested during this period. This represented 19.2% (601/3136) of obstetrics/gynecology admissions and 15.2% (339/2230) of neonatal admissions. Table 1 shows the occurrence of positive urine drug screens in mothers and newborns. There were 68.2% positive drug screens from the urine specimens submitted from mothers. Of the positive drug screens in mothers, 38.8% had more than one drug, with an average of 1.7 drugs per screen. For newborns, 63.1% were positive, with 21.1% having more than one drug. In both mothers and newborns (Table 2), the most prevalent drug detected was cocaine, present in 45.8% and 41.6% of all specimens, respectively. Cocaine was found as the only drug in 27.8% and 32.1% of the specimens submitted from mothers and newborns, respectively. An additional 29% of all maternal urine drug screens showed codeine, morphine, or methadone. These drugs were found with less-

Accepted for publication March 6, 1989.

er frequency in newborns (8.8% of all newborns screened). In contrast, meperidine and lidocaine were found more frequently in the newborns, accounting for findings in 21.5% of all urine drug screens.

A total of 191 mother-newborn pairs were identified from the 940 urine samples submitted from obstetrics/gynecology and neonatal services during the 13-month period. Of the specimens, 15.3% were received on the same day, 38.4% on the next day, 29.4% within 2 days, 14.7% within 3 days, and 2.1% within 4 days. Therefore, 83.2% of the specimens were received within 2 days. No drugs were detected for both mother and newborn in 15.2% of the pairs, in 59.7% of the pairs the mother's and newborn's urine contained any one drug in common, and 25.1% of the pairs showed no agreement in the findings. Cocaine was found in either the mother or newborn in 113 pairs (59.2%), and there was agreement between mother and newborn for cocaine in 84% of the pairs (Table 2). When cocaine was not found in both mother and newborn, it was otherwise found in the mother. Codeine (41 pairs) was found more frequently in the mother (88%) than in the newborn (12%). This was also true for salicylates, acetaminophen, and benzodiazepines, which were less prevalent overall. Other drugs that were infrequently found in mothers and newborns included phen-cyclidine (5 mothers and 1 newborn), antihistamines (7 mothers and 2 newborns), antidepressants (4 mothers and 1 newborn), phenothiazines (6 mothers and no newborns), antiepileptics (3 mothers and 1 newborn), dextromethorphan (1 mother and 1 newborn), benzotropine (1 mother and no newborns), propoxyphene (2 mothers and no newborns), guaifenesin (1 mother and no newborns), trimethoprim (1 mother and no newborns), quinine (1 mother and no newborns), and a caffeine level of more than 20 mg/L (no mothers and 2 newborns).

COMMENT

Our survey of urine drug testing results in mothers and newborns demonstrated that the clinical suspicion of drug involvement may be confirmed in about two thirds of the cases when either the mother or the newborn is

Drug Screen Results	Mothers	Newborns
Total No. of drug screens	601	339

Methadone	40 (6.7)	15 (4.4)
Amphetamines	13 (2.2)	2 (0.6)

tested. From the mother-newborn pair data, evidence of drug presence was found in 84.8% of the pairs. Testing both mothers and newborns would appear to yield greater confirmation of clinical suspicion.

The finding that nearly two thirds of submitted urine samples were positive for at least one drug is not unusual when compared with findings from all specimens received at this hospital (66.9% positive). Cocaine is found in 25% of the drug screens submitted from this hospital (all wards), suggesting that the 45.8% found in mothers was due to a higher prevalence or a more aggressive selection of these patients. Cocaine was a common drug found in two small selective surveys in the newborn.⁸⁴ Recently, we performed a blinded prevalence study of cocaine in urine for mothers admitted for delivery and in newborns of these mothers (unpublished data,

1988). The prevalence of a urine sample positive for cocaine was 9% and 5% in mothers and newborns (N = 152 pairs during 1 month), respectively, in contrast to 46% and 42% in clinically requested testing demonstrated in this article. Hence, clinical selection of cases will result in a fivefold to eightfold greater yield in positive cocaine urine screens.

Only cocaine showed a high concordance between mother and newborn. Several factors may explain this finding. Cocaine as the parent compound will pass through the placenta and is likely to be found in the newborn.⁵ The early pharmacologic signs and symptoms due to cocaine (irritability and hyperactivity) may signal the clinician to obtain a urine sample for toxicologic screening while the drug is still present. Another factor may be a slower hydrolysis of cocaine to ecognine methyl ester

Table 3.—Drugs Found and Concordance in Mother-Newborn Pairs

Drug	Drug Present		
	In Mother and Newborn, No. (% Concordant)	In Mother, Not Newborn, No. (% Discordant)	In Newborn, Not Mother, No. (% Discordant)

by plasma and liver esterases.^{6,7} This may result in prolonged elimination of cocaine and its metabolite, benzoylecgonine.

Pharmacologic factors that would predispose toward finding drugs in mother and not in the newborn include higher concentrations of drugs achieved in maternal tissues and kidneys, poor drug penetration through the placenta, and earlier sample collection in the mother. Delayed withdrawal signs that result in late collection of urine, and consequent negative results of analysis, may be the most important explanation

for absence of detection in the newborn. In a small study of specimens received by a hospital laboratory, the majority of drug screens were considered to be obtained too late for adequate detection.⁸ The finding of a drug in the newborn, but not the mother, might be explained by a longer residence time in the infant due to less developed hepatic clearance, or possibly a relatively higher distribution into infant body water.⁹⁻¹² Obviously, medications given during labor and after urine specimen collection would not be detected in mothers, but may appear in the newborn.

Of interest was the number of positive urine screens in newborns containing drugs that were likely to be administered to the mother while in the hospital. These included meperidine and acetaminophen as analgesics and lidocaine as a local anesthetic. The effects of these drugs on the newborn are not well studied, but meperidine is noted to cause neonatal respiratory depression when given more than 1 hour before delivery.¹³ Other narcotic analgesics (morphine, codeine, and methadone) were also frequently found, though some of these are probably related to drug abuse as well as medications. The prevalence of these drugs in toxicologic screens submitted from the entire hospital population is not dissimilar (8.8%, 7.1%, and 5.1%, respectively).

Many drugs were not found that otherwise might be expected because of the high prevalence of use. The rapid elimination of alcohol may explain its relative absence. Antihistamines, including antiemetics, could have been detected by the analytic methods used in this study, but few were found. Marijuana metabolite was not screened in this study, though it would further indicate the extent of drug abuse. In a large survey by interview, 9.5% of mothers reported using marijuana during pregnancy.¹⁴

This study suggests that cocaine is the most common drug found in the immediate peripartum period in this inner-city hospital. In addition, testing in both the mother and newborn should be attempted to improve diagnostic yield.

Non-Group A Streptococci in the Pharynx

Pathogens or Innocent Bystanders?

Gregory F. Hayden, MD; Thomas F. Murphy, MD; J. Owen Hendley, MD

• **Objective:** To determine whether β -hemolytic streptococci from groups other than A are an important cause of sporadic pharyngitis in children.

Design: Cross-sectional, case-referent survey.

Setting: General pediatric clinic at a military base in Ohio.

Participants: One hundred fifty children with symptomatic pharyngitis and 150 controls matched for age and time of presentation over a 20-month study period.

Interventions: None.

Measurements/Main Results: Anaerobic culture technique was used to improve isolation of β -hemolytic streptococci. Group A β -hemolytic streptococci were detected significantly more often among the ill children than among the controls (39% vs 16%, respectively). In contrast, non-group A β -hemolytic streptococci were isolated in similar frequency from the ill and control children (17% vs 21%, respectively). Non-group A β -hemolytic streptococci from groups B, C, F, and G were each isolated in similar frequency among the ill and control children. The isolation rate of non-group A organisms increased with age among both patients and controls.

Conclusions: Non-group A β -hemolytic streptococci seemed not to be an important cause of sporadic pharyngitis in this pediatric population.

(AJDC. 1989;143:794-797)

β -Hemolytic streptococci (BHS) from Lancefield group A are a well-recognized cause of pharyngitis in children.

Accepted for publication January 31, 1989.

From the Department of Pediatrics, Children's Medical Center, University of Virginia, Charlottesville, (Drs Hayden and Hendley); and the Department of Pediatrics, US Air Force Medical Center, Wright-Patterson AFB, Ohio (Dr Murphy).

The views expressed herein are those of the authors and do not necessarily reflect the views of the US Air Force or the Department of Defense.

Reprint requests to the Department of Pediatrics, Box 501, Children's Medical Center, University of Virginia, Charlottesville, VA 22908 (Dr Hayden).

Group A organisms can colonize the pharynx of asymptomatic children, but are isolated more commonly from children with pharyngitis than from healthy controls. Streptococci from Lancefield groups other than A have been associated with outbreaks of pharyngitis,¹⁻⁶ often with foodborne spread, but the role of these non-group A organisms in causing sporadic pharyngitis in children remains uncertain.⁶ Recent studies using anaerobic culture methods have demonstrated that BHS from groups other than A are frequently present in the pharynx of children with symptomatic pharyngitis, and further, that many such isolates of non-group A BHS will be missed if only the traditional aerobic method is used.⁷⁻¹²

The purpose of this article is to present the results of a study utilizing sensitive anaerobic culture methods to assess whether non-group A organisms were more common in the throats of children with sporadic pharyngitis than among carefully matched controls without pharyngitis.

PATIENTS AND METHODS

Population

One hundred fifty children with symptomatic pharyngitis who were seen by one of us (T.F.M.) at the Pediatric Clinic at Wright-Patterson AFB near Dayton, Ohio, were recruited for study during a 20-month period (February 1984 through October 1985). One hundred fifty children being seen at the same clinic for well care or a complaint unrelated to the respiratory tract who were matched to patients for age (within 1 year) and month of presentation were recruited to be controls and provided appropriate informed consent.

Clinical Evaluation

The clinical features of illness for each child with symptomatic pharyngitis were recorded on a standard, preprinted form. His-

torical items noted as being present or absent included fever, chills, sore throat, runny/stuffy nose, hoarseness or change in voice, headache, muscle aches, abdominal pain, vomiting, and diarrhea. On physical examination, the following features were noted as present or absent: tonsillar exudate, palatal petechiae, vesicles in the pharynx, tender cervical lymph nodes, otitis media, and exanthem.

Bacteriology

A throat culture was obtained from each patient and control by vigorously swabbing the posterior pharynx and tonsillar area with a rayon-tipped swab. Each swab was sent to the laboratory in modified Stuart's transport medium and inoculated within 6 hours onto a 5% sheep blood agar plate with an agar stab in the area streaked with the swab to highlight β -hemolysis beneath the surface of the agar. Following inoculation the plates were placed in an anaerobic environment (Anaerobic Gas Pak System, Baltimore Biologic Laboratory, Cockeysville, Md) and incubated at 35°C for 18 to 24 hours before reading. Plates showing no colonies with β -hemolysis were incubated in the anaerobic jar for an additional 24 hours before being discarded as negative. The Lancefield group of streptococci in β -hemolytic colonies was demonstrated using latex agglutination following enzymatic extraction of the group specific antigen (Streptex; Wellcome Diagnostics, Research Triangle Park, NC).

Statistical Analysis

Characteristics of the patients and controls were compared using χ^2 analysis or the Fisher Exact Test.

RESULTS

The 150 patients with pharyngitis were similar to the 150 controls in age (mean, 11.0 years in both groups), gender (41% and 49% males, respectively), and calendar month when sampled.

Group A BHS were isolated from the pharynx of 58 (39%) patients with pharyngitis and from 24 (16%) controls

Table 1.—Isolation Rate of β -Hemolytic Streptococci (BHS) by Lancefield Group From Throat Cultures From 150 Patients With Pharyngitis and 150 Controls

BHS Isolated	No. (%) of Patients With Pharyngitis*	No. (%) of Controls†	P‡
Group A	58 (39)	24 (16)	<.001
Non-group A (total)	25 (17)	32 (21)	
Group B	3 (2)	1 (1)	NS
Group C	7 (5)	12 (8)	
Group F	8 (5)	12 (8)	
Group G	8 (5)	8 (5)	

*Four children whose cultures contained streptococci belonging to two groups (A/F, A/F, A/F, and B/G) are counted in both groups.

†Three children whose cultures contained streptococci belonging to two groups (A/C, A/F, and F/G) are counted in both groups.

‡NS indicates not significant.

Table 2.—Clinical Features of Illness in Patients With Pharyngitis According to Throat Culture Result: β -Hemolytic Streptococci Isolated*

Clinical Feature	Group A (n=55)†	None (n=70)	Group Other Than A (n=22)†
Exanthem	15‡	1	0
Fever	76‡	46	32

Abdominal pain	27	16	23
Diarrhea	4	3	5

*Percentages of patients with each clinical feature are shown.

†Three patients from whom β -hemolytic streptococci from both group A and another group were isolated are excluded.

‡ $P<.05$.

($P<.001$; Table 1). In contrast, BHS of groups other than A were isolated from 17% of patients and from 21% of controls ($P>.05$). The serogroups of the non-group A BHS in patients were also similar to those in controls. Group B BHS were detected in 1% to 2% and groups C, F, and G were present in 5% to 8% of both patients and controls (Table 1). The isolations of non-group A BHS were scattered throughout the 20-month study period. The numbers of children cultured each month varied according to our clinic schedule and illness patterns in the community, with little seasonal variation in the isolation rate of

non-group A BHS among the ill children.

Age was an important variable in the frequency of detection of BHS of both group A and groups other than A. The isolation rate of group A streptococci from both ill and well children was highest in the 5- to 9-year-old age group and declined with increasing age (Figure). In contrast, the isolation rate of non-group A organisms increased with age in patients and controls. Non-group A BHS were isolated from 7 (33%) of 21 controls 15 to 19 years old. The clinical signs and symptoms of illness in the 150 patients with pharyngitis were ana-

lyzed according to throat culture results. The 55 patients from whom group A BHS were isolated were more likely to manifest fever, vomiting, palatal petechiae, tender cervical lymphadenitis, and scarlatinaform rash than were the 70 patients from whom no BHS were isolated (Table 2, $P<.05$). In contrast, the clinical manifestations in patients with non-group A isolates were similar to those in patients with no BHS detected ($P>.05$). Patients with non-group A isolates were much less likely to have fever than were patients with group A isolates (32% vs 76%, $P<.05$), but the clinical characteristics of these two groups were otherwise not statistically significantly different ($P>.05$).

COMMENT

Detection of non-group A BHS in the throats of patients with pharyngitis is insufficient to prove a causative role in the illness. Such patients could be carriers of non-group A organisms with an illness caused by another agent, such as a respiratory virus. A higher prevalence (isolation rate) of non-group A BHS in throats of patients with pharyngitis than in controls without pharyngitis would suggest a causative role for non-group A BHS in sporadic pharyngitis. In this study, the prevalence of non-group A organisms detected with sensitive anaerobic incubation in patients with sporadic pharyngitis was essentially the same as the prevalence in age- and season-matched controls. This finding does not support the hypothesis that non-group A BHS play an important causative role in sporadic pharyngitis in children.

Much of the evidence suggesting that non-group A BHS cause pharyngitis has derived from reports of outbreaks of illness. For example, in one foodborne outbreak of pharyngitis,² group G BHS were isolated from 63% of a sample of ill conventioners and from only 2% of persons without pharyngitis. Hill et al⁴ described another foodborne outbreak in which group G BHS were isolated from the throats of 64% of college students with pharyngitis compared to 23% of randomly selected controls.

In contrast, most epidemiologic studies of sporadic pharyngitis have found little difference in prevalence of non-group A BHS in sick vs well persons.

Rates of isolation of group A (left) and non-group A (right) β -hemolytic streptococci (BHS) from the throats of ill and well children according to age group.

Hable et al,¹³ Glezen et al,¹⁴ Stewart and Moghadam,¹⁵ and McMillan et al,¹⁶ using standard aerobic incubation of culture plates, isolated non-group A BHS as often from healthy control children as from children with symptomatic pharyngitis. The Commission of Acute Respiratory Disease likewise observed no significant increase in the isolation rate of non-group A BHS from soldiers with acute respiratory disease compared with normal soldiers.¹⁷ Glezen et al,¹⁸ however, isolated non-group A organisms from 10.8% of university students admitted to the infirmary with pharyngitis and from only 0.2% of asymptomatic controls. Likewise, Putto¹⁹ detected non-group A BHS among 21% of children with febrile exudative tonsillitis and among only 11% of 92 controls without pharyngitis.

In this study, the prevalence of non-group A BHS in the throat was markedly influenced by age (Figure), emphasizing the importance of matching for age in epidemiologic studies of non-group A BHS. The prevalence in adolescents, regardless of whether they were well or ill, was more than double the prevalence in grammar school children. This relationship between age and prevalence of non-group A BHS has been suggested in earlier work from university student health centers.^{20,21}

Regarding group A BHS, a serologic response to streptococcal extracellular

antigens is an accepted means of differentiating invasive infection from superficial colonization.²² Whether serologic testing can be used in similar fashion to confirm infection with non-group A BHS is less certain. Some patients with pharyngitis and a throat culture positive for non-group A BHS have been shown to respond serologically to streptococcal extracellular antigens in earlier studies.^{17,18,23-25} Some group C and G organisms produce streptolysin O that is antigenically similar to that produced by group A organisms,²⁶ so that a rise in antistreptolysin O titer may potentially be a useful indication of infection with these organisms. Benjamin and Perriello³ reported an outbreak of pharyngitis at a boarding school in which students who were culture-positive for group C BHS had higher antistreptolysin O titers than culture-negative students. However, culture-positive students had similar titers regardless of whether they were symptomatic or asymptomatic, and the titers did not rise during a 3-week period of observation.

After obtaining appropriate informed consent, we examined acute and convalescent serum specimens obtained from 67 children with symptomatic pharyngitis for antistreptolysin O and antidesoxyribonuclease B antibodies using standard microtitration methods (G.F.H. and J.O.H., unpublished data,

1983).^{27,28} The dilution increments tested were 1:60, 1:85, 1:120, 1:170, etc. A rise in titer of two dilution increments or greater from acute to convalescent serum was defined as evidence for a serologic response to infection. Nine (56%) of 16 children whose anaerobic culture contained group A BHS demonstrated a significant titer rise in either antistreptolysin O or antidesoxyribonuclease B antibodies. Only 1 (6%) of 18 patients with non-group A BHS showed a similar titer rise ($P < .01$). The 18 non-group A isolates included 3 from group B, 3 from group C, 7 from group F, 1 from group G, and 4 bacitracin-resistant BHS which were not grouped serologically. Difficulty arises in interpreting these apparently negative findings, however, because the extracellular products of many non-group A BHS either differ from those of group A organisms or are unknown.²⁹ The serologic tests that have proved useful in evaluating possible infection with group A BHS may be inappropriate for assessing infection with non-group A organisms. More definitive serologic documentation of infection with non-group A BHS must await identification of the cellular and extracellular products of these organisms with development of the relevant serologic assays.

A radioimmunoassay has been developed to detect antibodies to group C streptococcal carbohydrate, but the assay is not specific for acute infection with group C organisms.³⁰ Rises in antibody levels have been detected after asymptomatic carriage of group C BHS and after group A streptococcal pharyngitis. A recently developed enzyme-linked immunosorbent technique to detect antibodies to the group C and G carbohydrates seems to be more specific and may prove more useful.³¹⁻³²

A prompt clinical response to antimicrobial therapy would provide indirect evidence that non-group A BHS cause pharyngitis. In one previous study, antibiotic therapy seemed to reduce the duration and severity of pharyngitis in patients from whom group B organisms were isolated.³³ In another study, however, there was no clear-cut clinical response to penicillin among children with non-group A isolates.¹⁹ Whether antimicrobial therapy is useful in children with pharyngitis and non-group A BHS

on throat culture remains uncertain. Because the isolation rate of non-group A BHS increases with age, additional placebo-controlled treatment trials of patients with pharyngitis and non-group A BHS on culture should most logically be conducted among adolescents and young adults. Such trials will, it is hoped, provide a clearer answer as

to the advisability of antibiotic therapy.

CONCLUSION

Non-group A BHS were isolated as often from the throats of age- and season-matched controls as from children with sporadic, symptomatic pharyngitis. Evidence from localized outbreaks of pharyngitis, however, suggests that

these organisms can cause pharyngitis in some instances. Clarification of the role, if any, of non-group A BHS in causing nonepidemic pharyngitis in children will require further study of the cellular and extracellular antigens of these organisms along with documentation of children's serologic responses to apparent infection.

Epidemiology of a Cluster of Henoch-Schönlein Purpura

Thomas A. Farley, MD; Sheila Gillespie, MSN; Madjid Rasoulpour, MD; Narda Tolentino, MSPH; James L. Hadler, MD, MPH; Eugene Hurwitz, MD

• We investigated a case cluster of Henoch-Schönlein purpura that occurred in Connecticut during the fall and winter of 1987-1988. In Hartford County, where the case finding was most complete, 16 children were identified with disease onset during the 7-month cluster period (incidence, 1.7 cases per 10 000 children per year) compared with only 3 children with disease onset during the preceding 7 months. The incidence in Hartford County was higher among urban (4.8/10 000) and Hispanic (8.6/10 000) children and children in lower socioeconomic groups (6.9/10 000) than among suburban children or children in higher socioeconomic or different racial groups (0.9 to 1.1 per 10 000). We performed a case-control study involving 14 of the 16 case children from Hartford County, 10 case children from nearby areas, and 47 control children matched to the case children by age and race. Case children were more likely than control children to have had a sore throat during the month before the onset of Henoch-Schönlein purpura (52% vs 22%; odds ratio, 3.8; 95% confidence interval, 1.1 to 13). This difference and other smaller differences between case and control children suggest that the cluster may have been caused by person-to-person spread of an infectious agent of the respiratory tract to susceptible hosts. To our knowledge this is the first report of a cluster of Henoch-Schönlein purpura, and it provides clues for a better understanding of the etiology and epidemiology of the disease.

(AJDC. 1989;143:798-803)

Henoch-Schönlein Purpura (HSP) is a syndrome of unknown etiology that primarily affects children.^{1,2} Henoch-Schönlein purpura typically presents as a raised purpuric rash most prominent on the buttocks and lower legs, usually associated with crampy abdominal pain, arthritis, and/or hematuria.² A small percentage of children with HSP experience serious complications, such as intussusception, gastrointestinal hemorrhage, or chronic glomerulonephritis.^{2,4}

Although HSP was first described in the early 1800s, little is known of its etiology or epidemiology. It is believed that HSP is caused by an IgA-mediated immune response to a variety of foreign antigens.^{5,7} Isolated case reports have suggested links to specific exposures, such as drugs or infections,^{8,12} but no causative agent is apparent in the vast majority of cases. Henoch-Schönlein purpura is not generally a reportable disease, and its incidence in the community is unknown. We know of no previous reports of clusters or epidemics of HSP.

In November 1987, the Connecticut Department of Health Services was notified of four Hispanic children seen with HSP at a single medical center over a 2-week period. Other cases identified by contacting area pediatricians suggested

the presence of a cluster in the city of Hartford and the surrounding county by the same name. We investigated this cluster and carried out a case-control study in an attempt to describe the basic epidemiology of the illness and identify risk factors associated with its occurrence.

METHODS

Descriptive Epidemiology

In Hartford County we identified cases of HSP in children by telephoning all pediatricians in primary care practice and pediatricians on the staff of all general hospitals. Physicians were called between December 1, 1987, and January 30, 1988, and were asked to report cases of HSP seen since January 1987 and to continue reporting new cases through the end of 1988. All pediatricians were again contacted by mail in August 1988 to encourage continued reporting. The data presented herein represent those cases reported as of September 15, 1988.

A case was defined as a child under age 15 years who had received a physician diagnosis of HSP and who had the following signs and symptoms: (1) a vasculitic or purpuric rash most prominent on the buttocks or lower legs and (2) hematuria, abdominal pain, or joint pain. The HSP onset day was defined as the day the first of these symptoms or signs was noted. Cluster-related cases were defined as those cases with HSP onset between August 1, 1987, and February 29, 1988.

Incidence rates per 10 000 children under age 15 years per year were calculated by various demographic features in Hartford County. Population estimates for children under age 15 years by race and census tract were taken from the 1980 census.

Since the cluster was not clearly confined to Hartford County, we also attempted to identify cases that occurred in 1987 and 1988 in the remainder of the state. In the other counties in Connecticut we sent letters requesting case reports to all pediatricians and family practitioners and telephoned pediatricians and family practitioners in all teaching

Presented in part at the 1988 Epidemic Intelligence Service Conference, Centers for Disease Control, Atlanta, Ga, April 18, 1988.

Reprints not available.

hospitals. In addition, to provide a comparison with the city of Hartford, we telephoned all practicing primary care pediatricians in the cities of Bridgeport and New Haven, which are demographically similar to Hartford.

Case Series and Case-Control Study

We reviewed inpatient and outpatient records on 14 of the 16 case children in Hartford County and 10 cluster-related case children who lived within 30 miles of Hartford County. Parents of these children were also interviewed to determine the frequency, severity, and duration of symptoms.

The same 24 children in the case series were also included in the case-control study. For each of 23 case children, 2 control children matched to the case child by age (± 1 year) and by race/ethnicity were randomly selected from the active medical records of the case child's primary care provider. Only 1 control child could be matched with the remaining case child. Parents of case and control children were interviewed using a standard questionnaire that collected information on some 30 different items, including the following: antecedent symptoms, drugs, home remedies, foods, insect bites, travel, and school or day-care attendance in the month prior to the case child's HSP onset day. Information was also obtained on home environment, drinking water supply, illness in family members, and the child's medical history. The interviews took place a median of 38 days after the onset of HSP, with a range of 2 to 122 days.

At the time of the interview and after informed consent was obtained, blood samples were drawn from 21 of the 24 case children and 18 participating Hartford County control children. This blood was taken more than 2 weeks after HSP onset in 17 of the 21 case children and between 2 and 7 days after HSP onset in the other 4. The sera were stored and later tested using complement fixation and indirect fluorescent antibody techniques for antibodies to the following agents: adenovirus, coxsackievirus (serotypes A16 and B1 to B6), *Legionella pneumophila*, parainfluenza (serotypes 1 to 3), parvovirus B19, *Mycoplasma pneumoniae*, and group A *Streptococcus*. Evidence of recent streptococcal infection was defined as a reciprocal antistreptolysin O or anti-deoxyribonuclease B titer of 320 or greater in any serum specimen.

In our estimate of the risk of illness in Hartford County by race/ethnicity, we controlled for socioeconomic status (census tract median household income greater or less than \$10 000 per year) and area of residence (Hartford city vs surrounding towns) by creating stratified 2×2 tables and using Mantel-Haenszel estimators.¹³ In the case-control

Henoch-Schönlein purpura cases by month of onset in Connecticut from January 1987 through July 1988. Eight of the nine cases from Hartford city were in Hispanics.

study, odds ratios were calculated using both unmatched and matched-pair analysis. The results of these analyses were very similar; for simplicity, only the matched odds ratios are presented. Confidence intervals were calculated using methods of Robins et al.¹⁴ The potential of confounding as the cause of the association between acetaminophen and illness was evaluated with a conditional logistic regression model that included sore throat, fever, and acetaminophen use as independent variables. Because of the small number of children in the study, several case-control differences were found with substantial odds ratios, but the confidence interval overlapped 1.0. To avoid overlooking what may be clues to the etiology of HSP and to allow readers to judge whether these differences are important, we have reported these differences and provided both the odds ratios and confidence limits.

RESULTS

Descriptive Epidemiology

The identified cases of HSP are shown by month of onset in the Figure. Within Hartford County, 16 children became ill with HSP during the cluster time from August 1, 1987, to February 29, 1988 (incidence, 1.7/10 000 per year). This number of cases was more than five times the number of cases that occurred in the preceding 7 months (3 cases; incidence, 0.3/10 000 per year). The 16 cluster-related case children in-

cluded 10 (63%) boys and 6 (38%) girls; the median age was 5 years (range, 2 to 9 years). There were 7 white, 1 black, and 8 Hispanic children.

Hartford County contains the city of Hartford (population, 136 392), which has a primarily minority and lower-socioeconomic-group population, and Hartford's surrounding towns, which have a population that is overwhelmingly white and primarily of middle or upper-middle socioeconomic status. Eight of the nine Hartford city case children were Hispanic (all of Puerto Rican ancestry) and the other was black. These nine children themselves clustered in two distinct time periods within the larger cluster; six children became ill between October 15 and November 25, and three became ill between February 5 and February 21 (Figure). Included in this group were two pairs of siblings in Hispanic families.

Table 1 shows the incidence in Hartford County of cluster-related cases by area of residence, race, and census tract socioeconomic level. The incidence was particularly high in Hartford city (4.8/10 000), and within Hartford city the incidence was high among Hispanics (12/10 000) and children in lower-socioeconomic-group census tracts (7.0/10 000). Race, socioeconomic status, and area of residence were closely

*HSP indicates Henoch-Schönlein purpura.

†This is the number of cases per 10 000 children under 15 years of age per year.

correlated. However, when we attempted to control for socioeconomic status and area of residence, there was still a large relative risk for illness among Hispanics compared with blacks (relative risk, 8.6; 95% confidence interval [CI], 1.2 to 60) or whites (relative risk, 15.0; 95% CI, 0.6 to 36).

The time-clustering observed was not limited to Hartford County. In the seven other counties of Connecticut we identified 18 additional children in whom HSP occurred between August 1, 1987, and February 29, 1988, compared with only 8 children during the preceding 7 months (Figure). Sixteen of these children were white and 2 were Asian; none was Hispanic. During the entire time for which we collected reports, we identified no cases among Hispanic children (and only 2 cases in non-Hispanic children) in Bridgeport (population 142 546) and New Haven (population 126 109), which are demographically similar to Hartford and where our methods of finding cases were as intensive as in Hartford.

Case Series and Case-Control Study

For the 24 cluster-related case children included in the series, the most common clinical manifestations were rash (24 children, 100%) and joint pain and/or swelling (21 children, 88%), most commonly in the knees and ankles. Nineteen children (79%) complained of abdominal pain, but this pain lasted longer than 1 day in only 11 children

(46%). Nine children (38%) experienced vomiting. Of the 21 children with documented urinalyses, 4 (19%) had hematuria, defined as 10 red blood cells per high-power field. The median duration of rash was 14 days, with a range of 4 to 42 days; the median duration of joint symptoms was 5 days, with a range of 1 to 75 days. In addition to the two sibling pairs in the study, 1 child had a history of HSP in a first-degree relative.

Laboratory findings on these 24 children were consistent with the diagnosis of HSP. Eighteen (95%) of 19 children had platelet counts greater than $0.25 \times 10^{12}/L$. The erythrocyte sedimentation rate was greater than 35 mm/h in 5 (33%) of 15 children tested. Antinuclear antibodies and rheumatoid factor were not found in any of the 4 patients tested. The serum IgA level was elevated in 1 of 4 children and borderline in 1 other child. Eleven children had throat cultures sent at the time of diagnosis either because of a history of a sore throat or because of a concern that group A *Streptococcus* had a causal role in HSP. Six (55%) of these cultures were positive.

Eleven children (46%) were hospitalized for a median of 3 days, most often for diagnostic purposes or for abdominal pain or vomiting. Two children had barium enemas, which did not show intussusception. No other children had any major diagnostic or therapeutic procedures. At the time of the interview, one child had active nephritis; otherwise, none had had serious complications and

none had suffered sequelae.

The socioeconomic status and area of residence of the 24 case children and the 47 matched control children are presented in Table 2. The matching process had the effect of selecting controls who were very similar to cases in these demographic features.

The presence of antecedent symptoms and exposures to drugs in cases and controls is shown in Table 3. Case children were more likely than control children to have had a sore throat in the month prior to HSP onset (52% vs 22%; odds ratio [OR], 3.8; 95% CI, 1.1 to 13). This difference in the frequency of previous sore throat was seen in both Hispanics (43% vs 13%; OR, 2.4; 95% CI, 0.4 to 14) and non-Hispanics (56% vs 26%; OR, 5.5; 95% CI, 1.0 to 31) and was greater among children interviewed within 30 days of disease onset (6 [67%] of 9 cases vs 3 [21%] of 14 controls; OR, 9.6; 95% CI, 0.8 to 110).

Smaller differences between cases and controls were seen in the frequency of fever and nasal discharge (Table 3). Case children were no more likely than control children to have gastrointestinal complaints. Visits to physicians for illness during the 30 days prior to HSP onset were more common among cases than controls (30% vs 11%; OR, 3.3; 95% CI, 0.8 to 13). Six of the seven case children who made visits to physicians did so because of respiratory symptoms.

Acetaminophen was taken more often by case children than control children

Table 2.—Selected Demographic Features of HSP* Case and Control Children		
	No. (%) of Cases	No. (%) of Controls

*HSP indicates Henoch-Schönlein purpura.

during the month prior to HSP onset (61% vs 30%; OR, 2.9; Table 3). However, when we controlled for the presence of upper respiratory tract symptoms with a conditional logistic regression model, this difference was no longer present (OR, 1.6; 95% CI, 0.5 to 5.7). Cases and controls were approximately equally likely to have taken an antibiotic (17% vs 19%; OR, 0.8). Interestingly, of the 12 case children with sore throat, only 3 (25%) had taken an antibiotic, compared with 6 (60%) of the 10 control children with sore throat.

Three other differences between cases and controls were found that, due to small numbers, had marginal statistical power, but that were consistent with other findings suggestive of an infectious cause. Case children more frequently than control children had a household member with upper respiratory tract symptoms during the month before or the month after HSP onset (63% vs 38%; OR, 3.4; 95% CI, 1.0 to 12). Case children also tended to live in a more crowded environment, as indicat-

ed by households with more than one person per room, in spite of effective matching for socioeconomic status (38% vs 28%; OR, 2.0; 95% CI, 0.6 to 7.1). More case children than control children under the age of 5 years attended day care (7 [78%] of 9 cases vs 7 [47%] of 15 controls; OR, 3.3; 95% CI, 0.5 to 20). No other substantial differences between cases and controls were found for any of the other risk factors evaluated.

Because of the high incidence in Hispanic children, an effort was made to identify unusual ethnic foods or home remedies associated with illness. None was reported by parents of either cases or controls.

Antibody evidence of recent streptococcal infection (Table 4) was present slightly less often in cases than controls in Hartford city (56% vs 77%; OR, 0.7; 95% CI, 0.2 to 3.5) and in Hartford County as a whole (50% vs 67%; OR, 0.4; 95% CI, 0.1 to 2.3). However, evidence of recent streptococcal infection was present more often in both case and control children in the city of Hartford (15

[68%] of 22) than in case and control children in other towns (5 [40%] of 17; OR, 5.1; 95% CI, 1.1 to 26).

At the time of the interview, no more than two case children statewide had elevated levels of antibodies to any of the other agents listed in the "Methods" section. Blood was also available from the time of HSP onset for six case children, providing paired samples to test for antibody changes. One acute-convalescent pair showed a fourfold titer rise in antibody to *L pneumophila*. None of these six pairs showed a fourfold increase or decrease in antibody to any of the other agents, including group A *Streptococcus*. To determine the ability to make immunoglobulins to specific challenges, we tested serum samples from case and control children for antibody to cytomegalovirus and rubella. Approximately 75% of both case and control children had antibodies to these two viruses.

COMMENT

Although children with HSP generally recover uneventfully, severe complications can occur. In approximately 8% of children, gastrointestinal hemorrhage or intussusception occurs.² Twenty to forty percent of children have clinically apparent glomerulonephritis,^{2,3} and in 3% to 14% of these children disease progresses to chronic renal insufficiency.^{2,4} Henoch-Schönlein purpura was the cause of renal failure in 2% and 5% of groups of children undergoing hemodialysis in California and France, respectively.^{15,16} The importance of understanding the epidemiology, etiology, and pathogenesis of HSP lies in the potential prevention of renal failure in these children.

The clinical manifestations of the children in our study were similar to those in children in previously published case series.^{2,3} Although the character of the illness was typical, the pattern of occurrence of the disease in the population was not.

Our intensive case finding in Hartford County for 1987 placed the background incidence of HSP among children under age 15 years at approximately 0.2 to 1.0 cases per 10 000 children per year. This is comparable with the incidence of HSP found by Nielsen¹⁷ in a study of the epidemiology of HSP in Denmark. Nielsen found conflicting results regarding the pattern of disease occurrence but wrote that "the conclusion is clear: there is no clustering." In contrast, we were able to demonstrate a case cluster limited in time and space and centered in one ethnic group. While a seasonality of occurrence of the HSP has been described previously, with the winter months the peak time period,^{3,18} to our knowledge, this is the first published report of such a cluster.

Extremely high incidence rates were present in a single demographic group: lower-socioeconomic-group Hispanic children from the city of Hartford. When we attempted to control for urban environment and socioeconomic status, the incidence rate for Hispanics was still far higher than for white or black non-Hispanic children. It is possible that cases of HSP were missed in black children because the rash might be less prominent; however, a reporting artifact such as this could not explain the low observed rate in white non-Hispanic children. Thus, it appears that while socioeconomic or urban factors such as crowding may have contributed to the development of illness, some other factors associated with Hispanic children in this outbreak caused them to be at uniquely high risk for HSP.

Since the Hispanic children in our study were all of Puerto Rican ancestry, a possible explanation for their high incidence rates is that members of this ethnic group have a higher immunologic susceptibility to HSP than other Americans. This might explain the finding of two sibling pairs in Hispanic families with HSP. Other authors have noted HSP occurrence in two or more family

members.^{3,20} Alternatively, the sibling pairs and the other Hispanic children in the study may have been exposed to a common factor—such as an ethnic food or home remedy—that increases the likelihood of illness. While we carefully sought information about this kind of common exposure and found none, we are not certain that an exposure specific to this ethnic group did not take place.

Histologically, HSP is characterized by leukocytoclastic vasculitis,²¹ which is apparently caused by IgA immune complexes.^{6,22,26} Henoch-Schönlein purpura may occur when certain specific agents provoke an immune response in a predisposed host that leads to the formation of these IgA immune complexes.

The association between HSP and previous upper respiratory tract symptoms suggests that common exposure to an infectious agent that caused respiratory symptoms provided the immunologic stimulus for the development of HSP in the cluster-related case children. While previous case series have reported a high frequency of antecedent upper respiratory tract infection in children with HSP,^{2,3,18,19} we believe our study is the first to compare this frequency with that of a matched control group. It seems unlikely that the association with a previous upper respiratory tract infection can be explained by recall bias in view of the findings of the larger case-control differences among those families interviewed most recently and the association with previous physician visits, which are more objective indicators of illness.

If an upper respiratory tract infection was the inciting event in the development of HSP, it is not surprising that we also found a greater number of upper respiratory tract infections in other members of case households. The observed differences between case and control children in household crowding and day-care attendance (in spite of close socioeconomic matching) are also consistent with the hypothesis that the agent causing these upper respiratory tract infections is transmissible person-to-person in crowded settings.

Many infectious agents have been proposed as causes of HSP. It was previously thought that cases could often be linked to recent infection with group A *Streptococcus*.²⁷ Our investigation

produced three findings that provided some support for a relationship between group A *Streptococcus* and HSP in this cluster: (1) The organism was found on throat cultures of 6 of 11 case children. (2) Case children with sore throats received antibiotics less often than controls, suggesting a protective effect of antibiotics. (3) Serologic evidence of recent streptococcal infection was more frequent in Hartford city—the area with the highest incidence of HSP—than in the rest of Hartford County or in other areas of the state. However, these findings need to be interpreted cautiously because of the small numbers of children in this study. Furthermore, we were unable to show a greater frequency of elevated streptococcal antibody titers in cases than controls. This lack of association between streptococcal antibodies and HSP has also been found in a previous case-control study.²⁸ We believe, therefore, that although the data do not support a simple and direct causal role for group A *Streptococcus*, it remains possible that recent streptococcal infection was one contributing factor in the development of HSP in case children.

The absence in nearly all case children of antibodies to the other agents for which testing was performed suggests that they were unimportant in this cluster. In particular, we found nothing to support the role of parvovirus B19, which has recently been proposed as a cause of HSP.¹²

Overall, the findings of our case-control study are consistent with the conclusion that HSP can result from a reaction in a susceptible host to a communicable infectious agent. We believe that during periods of high prevalence of such an infectious agent, the interactions between host, agent, and environment could account for the type of case clustering we found. Similar investigations of HSP clusters are needed to better characterize risk factors for HSP and to identify agent(s) that have a causal role in this disease.

We thank Stanford T. Shulman, MD, and Robert A. Gunn, MD, MPH, for their help in this study.

Breast-feeding Pattern Among Indochinese Immigrants in Northern California

Eunice Romero-Gwynn, PhD

• A sharp decline in the rate of breast-feeding was documented among Indochinese mothers who migrated from Cambodia and Laos to a city in northern California. While 97.0% of the mothers breast-fed their last infant born in Indochina, only 26.1% and 22.4%, respectively, breast-fed their first and last infant born in the United States. Furthermore, only 3.8% of the mothers who were pregnant at the time of the study intended to breast-feed. The duration of breast-feeding decreased from an average of 20.4 months for the last infant born in Indochina to 8.7 months for the last infant born in the United States. After controlling for several sociodemographic variables, only formula samples distributed at hospital discharge had a significant association with formula feeding (odds ratio, 2.02). However, data on intention to breast-feed suggested that a clear cause-and-effect relationship may not exist. Factors related to cultural traditions and acculturation are offered as possible explanations for the decline in breast-feeding. Breast-feeding education for mothers and training for health professionals is recommended.

(AJDC. 1989;143:804-808)

Internal and international migration have been associated with improvement in family well-being and the diets of adults.^{1,3} However, changes in infant feeding among families who have emigrated from less industrialized to more industrialized settings have been less positive.⁴⁻¹⁰ The common pattern seen in most studies is a rapid decline in breast-feeding, coupled with an increase in use of commercial formula and other manufactured supplementary foods for infants after emigration. A decline in the rate of breast-feeding was documented by Evans et al,⁴ who studied mothers

who emigrated from northern India to England, and by Goel et al⁵ among Pakistani, Indian, Chinese, and African mothers who emigrated to Scotland. Among the groups who emigrated to the United Kingdom, the Chinese appeared to have experienced the greatest decline (from 98.0% to 2.0%) in breast-feeding before and after emigration. Other researchers have documented declines in breast-feeding among Asian mothers who emigrated to Sweden⁷ and to Australia,⁸ and among Mexican mothers who moved to the United States.^{9,10} A different trend was reported from two studies conducted in the mid-1980s among Turkish women who emigrated to Stockholm, Sweden,⁷ and Vietnamese mothers who emigrated to Australia.¹⁰ In both of these studies, mothers who emigrated had breast-feeding rates similar to the prevalent rate in the host society.

The present study was motivated by reports from nutrition education assistants working for the Expanded Food and Nutrition Education Program, who observed frequent use of formula among Indochinese families, and by our own observations in several homes. This study was planned to quantify the observations and to test the hypothesis that the incidence of breast-feeding among the refugee community had significantly declined as a result of emigration. Thus, the major purposes of the study were (1) to assess the incidence and duration of breast-feeding and weaning practices before and after emigration to the United States, and (2) to identify factors associated with both milk-feeding practice and weaning. The present report will focus on breast-feeding patterns before and after emigration. Weaning practices will be reported later in an article in preparation at this writing.

SUBJECTS AND METHODS

The sample consisted of 134 Indochinese refugee mothers who settled in a city in northern California. At the time of the study the refugee families were living in three large apartment complexes in one area of the city. Approval to conduct the study was obtained from the Human Subjects Committee of the University of California, Davis, and from local refugee community leaders.

The criteria for selection of mothers to participate in the study were that they must have at least one infant born in Indochina and at least one infant born in the United States. Mothers were selected after the completion of a door-to-door census in which the number of children born before and after emigration was ascertained. Mothers who met the criteria were then visited in their homes and invited to participate voluntarily in the study. Only 2 of the 136 selected mothers declined to participate. Since the intent of the study was to assess the pattern of infant feeding over time, mothers who had more than one infant born in the United States were asked about feeding practices for the first and last children born in the United States. Mothers who were pregnant at the time of the study (26 women) were asked if they had decided how they would feed their infant, and if so, what milk (breast, formula, both, other) they were planning to feed their infant after birth.

Data on infant feeding were collected using a questionnaire tested on Indochinese families who were from the same community but who did not meet the inclusion criteria. In the construction of the questionnaire, four members of the community were consulted regarding cultural appropriateness of the questions included. Individual interviews were conducted with each mother at home and in her native language (Hmong, Laotian, or Cambodian).

Statistical analysis consisted of frequency distributions, χ^2 analysis, and logistic regression.¹¹ Logistic regression is a nonlinear model that is used to explain binary dependent variables such as breast-feeding vs non-breast-feeding. The independent variables used in the regression analysis were as follows: parents' education, attendance to En-

Accepted for publication February 24, 1989.

English classes, family type (nuclear vs extended), years of residency in the United States, participation in the Supplemental Food Assistance Program for Women, Infants and Children (WIC) during pregnancy, and the receiving of formula samples at hospital discharge. Odds ratios (which indicate the likelihood of the occurrence of a given phenomenon: breast-feeding vs non-breast-feeding) were calculated using the coefficient obtained in the logistic regression analysis.¹² The Statistical Package for the Social Sciences¹³ and the BMDP¹¹ packages were used for computer analysis.

RESULTS

Description of the Sample

The sample consisted of 134 mothers and 348 children (134 last-born in Indochina before emigration, 134 first-born in the United States, and 80 last-born in the United States; 54 families had only one child born in the United States). The native languages of the mothers were Hmong (50.7%), Cambodian (32.1%), and Laotian (17.2%). Almost one half of the sample migrated with the parents of either the husband or wife or both. The majority of the mothers did not attend school in their country of origin; 24.4% had completed from 1 to 12 years of school. The majority of mothers (68.0%) had attended English classes in the United States for periods that varied from 1 to 36 months. Two percent of the mothers had enrolled in adult education classes or received other formal education in addition to English classes. Although the level of education of the husbands was higher than that of the wives, approximately one third of the husbands had received no formal education. More husbands than wives had attended school in the United States in addition to taking English classes offered for immigrants through local schools. The fertility rate among these families was high. The numbers of children born to them ranged from 2 to 12 (mean, 5.4 ± 2.2). The mean ages of the first and last children born in the United States were 2.4 years and 9.5 months, respectively.

Welfare was the main economic support for most families. Both husbands and wives practiced gardening in small lots around their apartment buildings and/or community gardens using land provided by local organizations. Medicinal herbs were invariably part of the garden, along with vegetables. Al-

	Infant Birthplace, %			
	Indochina (n = 134)	Firstborn (n = 134)	Last-Born (n = 80)	Unborn (n = 26)
Breast-fed				
Exclusive	94.0	17.1	16.2	3.8
Partial	3.9	9.0	6.2	0.0
Subtotal	97.9	26.1	22.4	3.8
Exclusive formula	2.1	73.9	77.6	96.2

though gardening mainly produced food for family consumption, some families were able to sell their produce in local markets. Families had access to food assistance programs such as the WIC and food stamps. Employment for either husband or wife was very rare; only 2.3% of the mothers had worked away from their homes.

Socialization among subgroups of immigrants sharing cultural traditions and languages (Hmong, Laotian, Cambodian) appeared to be very high. Groups of adults were often seen visiting inside their homes or in front of their apartments. Socializing with other ethnic groups seemed to be rare. However, a major means of contact with American culture was through mass media. Television sets and radios were observed in nearly every home; stereos and video-

cassette recorders were seen frequently.

Breast-feeding Before and After Emigration

Table 1 and the Figure show the incidence of exclusive breast-feeding, partial breast-feeding, and exclusive formula feeding for the last infant born in Indochina and for first and last infants born in the United States. They also show the breast-feeding intentions of those mothers who were pregnant at the time of the study. As can be seen in Table 1, 97.9% of the last infants born before emigration were breast-fed (94.0% exclusive breast-feeding and 3.9% partial breast-feeding), and 2.1% were fed milk other than breast milk. After emigration to the United States there was a sharp decline in breast-feed-

ing. Only about one sixth of the mothers breast-fed their first and last infant born in the United States. The trend continued toward an even greater decline since only 3.8% of the 26 women who were pregnant at the time of the study intended to breast-feed. Conversely, the number of mothers who fed their infants formula increased from 2.1% in Indochina to 73.9%, 77.6%, and 96.2% for the first, last, and expected infants in California, respectively. The duration of breast-feeding (in ever-breast-fed infants) decreased from an average of 20.4 months before migration to 8.7 months for the last infant born in the United States. A comparison of reasons for breast-feeding and for formula feeding is shown in Table 2. The two major reasons given by mothers for breast-feeding in their country of origin were related to the high cost or lack of availability of formula in their localities. Reasons given by mothers for formula feeding in the United States were (in order of frequency) intention to work, desire to attend school, lack of or insufficient milk, and breast infection. Other reasons given by smaller numbers of mothers are listed in Table 2.

Type and Source of Formula Used

Most mothers reported receiving formula samples at hospital discharge; 88.1% and 87.5% reported they had received samples for their first and last infant born in the United States, respectively. The types of formula given were (in order of frequency) Similac, Enfamil, SMA, Isomil, and Prosobee. Formula was obtained using WIC vouchers for 76.7% and 69.2% of the first- and last-born infants in the United States, respectively. Mothers who received formula from the WIC used it for different periods: 24.7% of them used it for 1 to 6 months, and 75.3% used it for 7 to 12 months. Families not participating in the WIC purchased formula for the entire feeding time. (The cost of feeding formula per infant per month is approximately \$70, or nearly \$850 per year, calculated in 1988 and based on the price of ready-to-feed formula that is commonly used by these families.)

Mothers were asked which, in their opinion, was the best milk for an infant. Their responses were "formula" (58.3%), "breast" (35.8%), "either one is

Reason	Infant Birthplace, No. (%)		
	Indochina	United States	
		Firstborn	Last-Born
Breast-feeding			
Formula very expensive	97 (77.6)	19 (82.7)	10 (76.9)

*Includes exclusive formula feeding (n = 99) plus formula supplemented with breast milk (n = 12).

†Includes exclusive formula feeding (n = 62) plus formula supplemented with breast milk (n = 5).

good" (5.0%), and "don't know" (0.9%). Table 2 shows reasons given by mothers for breast-feeding and for formula feeding their infants. It is important to note that the first reason given by most mothers for feeding breast milk was the high cost of formula; only 2 (15.4%) of the 13 mothers who planned to breast-feed their expected infant mentioned breast milk as being "better for baby's health."

The type of family (extended vs nuclear) and the type of formula given at hospital discharge were the only two variables significantly related to feeding mode. Mothers living in extended-family households (with parents of either spouse) were more likely to breast-feed than those living in nuclear-family households ($\chi^2 = 8.91$; $P = .002$). Thus, 65.6% of the mothers living with their parents breast-fed their infants, as opposed to 34.4% who breast-fed while living on their own. However, not all couples living with parents breast-fed; 35.6% of the couples who formula fed had their parents living with them.

Mothers who received formula samples at hospital discharge were less likely to breast-feed ($\chi^2 = 40.14$; $P = .001$); 98.0% of the mothers who formula fed at

home received formula at hospital discharge. While these statistics suggest an association, a cause-and-effect relationship cannot be inferred. None of the other characteristics of the family, such as education of the couple, years in the United States, number of children, attendance to English classes, ethnic subgroup (Hmong, Cambodian, Laotian), or participation in the WIC program, were related to the infant-feeding mode.

Results of the logistic regression analysis showed that mothers who received formula samples at hospital discharge were more likely to feed their infants formula than were mothers who did not receive such samples (odds ratio, 2.02; $P = .05$). The type of family (nuclear vs extended), which was a significant factor in the χ^2 analysis, was not significant in the regression analysis. None of the other independent variables studied showed any significant role in explaining feeding mode.

COMMENT

In the present study group, a sharp decline in breast-feeding began with the first infant born in the United States and continued with subsequent births.

Thus, while 97.7% of mothers breast-fed (94.0% breast-fed exclusively) their last infant born in Indochina, only 26.1% and 22.4%, respectively, breast-fed their first and last infants born in the United States. Furthermore, only 3.8% of the mothers who were pregnant at the time of the study were planning to breast-feed.

Our statistics demonstrating a decline in the rate of breast-feeding after emigration are similar to those reported by Evans et al⁴ and Goel et al⁶ among Indian and Chinese mothers who emigrated to the United Kingdom. For example, the incidence found by Evans et al⁴ among Indian mothers was 92.0% before emigration and 30.0% after emigration. The duration of breast-feeding among these mothers decreased from 10.2 months in India to 1.1 months in the United Kingdom. In our sample, the average duration of breast-feeding was 20.4 months for the last infant born in Indochina, as opposed to 8.7 months for the 18 mothers who breast-fed their last infant born in California. Our figures for breast-feeding incidence are lower than those reported from Mexican mothers who have emigrated to California⁹ and Indochinese mothers (mostly from Vietnam) who have emigrated to Australia.^{8,10} Mathews and Manderson⁸ reported a breast-feeding incidence of 75.0% and 40.0% (for ever-breast-fed infants) before emigration from Indochina and after settlement in Sydney, Australia, respectively. The study by Reynolds et al¹⁰ in Perth, Australia, seems to be the first published research documenting no decrease in breast-feeding after emigration. The authors even suggest the possibility that an increase may have taken place. Their figure for breast-feeding initiation among these Vietnamese mothers was 81.0%. The large difference in breast-feeding initiation between our sample and that studied by Mathews and Manderson⁸ and Reynolds et al¹⁰ may be due to differences in the samples. The mothers in those two studies were primarily Vietnamese, while the mothers in the present study were all Laotian or Cambodian. Although the level of education was not reported by Mathews and Manderson⁸ or Reynolds et al,¹⁰ it is known that, in general, the persons who emigrated from Vietnam in the 1970s

tended to be educated, wealthy, and greatly influenced by European culture. The refugee mothers in our sample were mainly from villages and remote areas of Laos and Cambodia. Approximately two thirds of them had not received formal education.

Reynolds et al¹⁰ indicated that the Vietnamese women studied in Perth assimilated the infant-feeding practices of the host communities, as the incidence and duration of breast-feeding in their sample was very close to that of the native Australian mothers in Perth (81.0% vs 82.0%). Thus, it is possible that the Vietnamese immigrants were integrated into the Perth community and had the opportunity to perceive accurately the local infant-feeding practices prevalent there. The integration of families in our sample with a cross-section of the large community in Stockton seemed to be very limited. This may be due to limited English skills, lack or limited means of transportation from housing, or lack of or limited participation in the labor force.

While in many other countries breast-feeding is commonly practiced in public, in the United States breast-feeding is seen neither in public nor in the mass media. Bottle-feeding, however, is very often seen in public places in the United States, creating an inaccurate representation, and possibly projecting the notion that breast-feeding is not practiced in the United States.

Although there are no data on breast-feeding among the general population of mothers in Stockton, the 1984 data obtained by Martinez and Krieger¹⁴ on low-income mothers (<\$7000 per year) indicate a breast-feeding incidence of 36.6% vs 71.8% for mothers in the above-\$25 000 income bracket. If the national figures for the lowest income group are close to the incidence of breast-feeding among low-income families in Stockton, the assimilation explanation given by Reynolds et al¹⁰ may apply to our sample of mothers. Their rates for ever having breast-fed were 26.1% and 22.4%, respectively, for the first and last infants born in the United States. The assimilation concept may explain the difference between the breast-feeding rates among our sample of Indochinese persons and the Mexican immigrant mothers studied by Kokinos and Dewey.⁹ The

breast-feeding incidence among the Mexican mothers in first infants born in the United States was 58.0%, vs 26.1% for the first infants born in the United States in our Indochinese sample. However, the emigration characteristics are different among these two groups of mothers. As reported by Kokinos and Dewey,⁹ many of the Mexican mothers return to Mexico annually. This and the large Mexican culture existing in California may be delaying the assimilation of infant-feeding practices prevailing among other groups with limited income and education in the United States. In contrast, the emigration of our Indochinese subjects was more permanent because of their refugee status, which automatically granted them permanent residence in the United States. The distance between the United States and Indochina and the political situation in Indochina also severely limit contact with their original culture.

Another possible explanation for the decline in the popularity of breast-feeding could be the availability of infant formula in commercial outlets, hospitals, and supplementary food programs. Evans et al,⁴ explaining the decline in the rate of breast-feeding among Indian mothers who emigrated to England, claimed that the availability of an alternative to human milk and the means to obtain it may be the major cause for emigrant mothers to cease breast-feeding. When mothers in our sample were asked why they breast-fed their infants in Indochina, the two main reasons given were that formula was too expensive and/or it was not available (Table 2). No mention was made of a tradition of breast-feeding, nor was mention made of any nutritional or health-related attribute of human milk over other milk. This seems to suggest that the mothers in our sample did not know of the substantial advantages of human milk over commercial formula and that they would have fed formula to their infants in their native countries had it been available at an affordable price.

According to mothers' reports, in the United States formula samples were given at hospital discharge to 81.1% and 87.5%, respectively, of the mothers for their first and last infants born in the United States. This was the only variable showing statistical significance in

the logistic regression analysis when sociodemographic variables were controlled for. However, a clear cause-and-effect relationship cannot be deduced, as it is not known to what extent formula samples were accepted because mothers had already decided not to breast-feed their infants. In our study, prepartum breast-feeding intentions were not assessed for the first and last children born in the United States. However, 96.2% of the mothers (n=26) who were pregnant at the time of the study expressed their intention to feed formula exclusively to their expected infant.

A final possible explanation may be related to Indochinese cultural beliefs and practices surrounding delivery and puerperium.^{8,15} According to Indochinese beliefs, puerperium is a time of vulnerability for the mother, who is believed to lose "vital energy and heat" and to enter into a "cold state."¹⁵ This is counteracted by keeping her warm and confined for at least 1 month in a room that is sealed against wind and drafts. The woman is fed chicken and other foods considered "hot."^{8,15} She receives steam baths and is kept very warm with the heat of burning charcoal, a practice known as "mother roasting."^{8,15} Colostrum is not fed to the infant, as it is considered unhealthy. Thus, colostrum is usually expressed and discarded. The newborn is fed by another nursing mother or is fed rice water for the first 2 or 3 days. Breast-feeding is initiated when the production of colostrum ceases.⁸

A traditional practice in support of breast-feeding is that the mother's mother takes over the household work and cares for the family so the new mother can rest and care for her new infant.

It is not known to what extent an Indochinese mother's negative attitude toward feeding colostrum to the infant may be interpreted by the American hospital staff as a refusal to breast-feed, resulting in formula feeding during the hospital stay. Formula feeding in turn may be interpreted by the mother as the accepted infant-feeding practice in the United States. However, while this may have been the case for the first delivery in the United States, our data on intentions to breast-feed among women who were pregnant at the time of the study suggest that most mothers enter the hospital having made the decision to formula feed already.

Our study of a group of Indochinese immigrant mothers of childbearing age has demonstrated that their rate of breast-feeding has declined sharply following emigration to the United States. While the statistical analysis identifies formula samples given at hospital discharge as the major factor associated with the change, alternative explanations include the assimilation of the low breast-feeding rate typical of families with limited income and education in the United States, a distorted perception of formula feeding as the American infant-feeding norm, a disruption of traditional rituals surrounding partum and puerpe-

rium by delivery in the hospital vs traditional home delivery in Indochina, and, above all, lack or limited awareness of the advantages of breast-feeding for the health of the infant and the mother. The retrospective nature of the present study, which was based on mothers' recall of events, should be taken into account when interpreting our results. Prospective follow-up studies are recommended. Education on the importance of human milk, including colostrum, seems to be necessary for Indochinese mothers. Use of audiovisual aids showing American women breast-feeding may be helpful in changing these mothers' apparently mistaken perception of recommended infant feeding practices in the United States. Training for hospital staff regarding cultural factors and ways to assist mothers in initiating breast-feeding in the hospital, limitation of infant formula supplementation in the hospital, and limitation of the distribution of formula samples at hospital discharge are recommended.

We thank the Laotian and Cambodian families who accepted us into their homes for interviews; Yee Lo, who conducted interviews with the mothers in their native languages; Denise Di Pietro for assistance in technical editing and preparation of the manuscript; Edward Dolber-Smith for assistance in data analysis; and Lola Lawson, MA, former coordinator of the Expanded Food and Nutrition Education Program, for her interest in the Indochinese community and support given to the initiation of this study. Amy Block Joy, PhD, director of the California Expanded Food and Nutrition Education Program, provided support in conducting the present study.

Educational Interventions

Hugh D. Allen, MD, Columbus, Ohio
Fredric Burg, MD, Philadelphia, Pa
Harold Levine, MPA, Galveston, Tex
Barbara Starfield, MD, Baltimore, Md
Larrie W. Greenberg, MD, Washington, DC

Purpose.—This department is intended to share information concerning educational efforts in the broad field of pediatrics. We welcome studies on the following topics: undergraduate and graduate education in medicine and allied health occupations; continuing education of health professionals; education of patients and families; and health education for the general public, the community, and organizations that contribute to the promotion and improvement of the health of children.

Editorial Comment.—*Many training programs offer continuity clinic experiences for resident education. Some residents may grumble that this experience does not reflect the "real world." In this study, Wilson et al address this question and find, at least in their setting, that such an experience does indeed reflect the primary care experiences met by private pediatric practices in their community.*—H.D.A.

Does a Residents' Continuity Clinic Provide Primary Care?

Modena E. H. Wilson, MD, MS, MPH; Jonathan P. Weiner, DrPH; Joan C. Bender, MD;
Steven K. Bergstrom, MD; Barbara H. Starfield, MD, MPH

• Pediatric residents are required to care for a group of children over a period of time. For many, this "continuity" experience is in a hospital outpatient department that may or may not provide primary care. We applied a measure of primary care to the Primary Care Clinic, the continuity clinic at The Johns Hopkins Hospital, Baltimore, Md, and found that it compared favorably with private pediatric practices in the Baltimore area, providing significantly more "principal care" (93% vs 84.5% of encounters), and to the Harriet Lane Home walk-in clinic, where only 51% of encounters were "principal care." The Primary Care Clinic scored higher on a primary care index, a measure of the extent to which the facility serves as a primary care source for patients, suggesting that hospital-based training can provide residents with an opportunity to provide primary care.

Presented in part at the 24th Annual Meeting of the Ambulatory Pediatric Association, San Francisco, Calif, May 2, 1984.

Reprints not available.

To balance the subspecialization of the past 2 decades¹ and to meet the requirements of the Accreditation Council for Graduate Medical Education for continuous care of patients,² pediatric resident training in many hospital-based outpatient clinics has been restructured to include provision of ongoing care for children, both for health maintenance and acute problems. These "continuity clinics" are organized within the hospital or the pediatrics department of the medical school to provide experience that will mimic as closely as possible pediatric practice as it takes place in the community.

One characteristic of ambulatory pediatric practice is the provision of primary care.^{3,5} Therefore, one measure of the appropriateness of a hospital-based clinic as an ambulatory or continuity training site may be the degree to which it provides primary care. We are aware of few previous reports of the measurement of primary care or its attributes in teaching clinics.^{6,7}

Although definitions vary, it is generally accepted that the concept of primary care refers to care that is accessible (including being open to new nonreferred patients), comprehensive (including both health maintenance and care for common acute illnesses), coordinated, and longitudinal.^{8,9} While there

appears to be consensus on what is meant by primary care, there is as yet little agreement on how to measure it.⁹ A list of indicators has been offered that, if present, suggest the potential for providing primary care.¹⁰ Physicians have made judgments about whether or not they provide the "majority" of care for a series of patients.¹¹

Measurement of the process of care has also been attempted. Attributes of primary care, for instance, continuity (longitudinality) and coordination, have been measured.^{6,7,12}

Weiner and Starfield¹³ developed an index of primary care that focuses on the process of practice and can be applied to a series of patient encounters with a practitioner, an office, or a clinic of any specialty. The index has been used previously to measure the degree to which a large number of office-based private practitioners in the Baltimore, Md, area, including pediatricians, are providing primary care. Based on observations made at patient encounters, among the advantages of the index are that it includes several aspects of primary care: accessibility, comprehensiveness, and longitudinality.

We used the index to measure the level of primary care in the Harriet Lane Pediatric Primary Care Clinic (PCC), the pediatrics house officers' continuity

clinic at The Johns Hopkins Hospital. The PCC is located in a tertiary care teaching center with a large pediatric house staff and a subspecialty and research orientation. Forty percent of the patients, who are predominantly from poor urban families, have at least one chronic problem. For these reasons and others, it was feared that the PCC might fail to provide the high level of primary care that was intended. This evaluation was designed to provide a basis for change if such was required.

PATIENTS AND METHODS

Data for calculation of an index of primary care, as previously reported, are obtained from patient encounter logs and based on the answers to questions addressed to consecutively seen patients or their parents.¹³ With wording modified for use in an exclusively pediatric clinic study, the questions were as follows:

1. Is this the child's first visit to this clinic?
2. Did a doctor from some place outside of this hospital send you to this clinic?
3. The last time this child had a regular checkup, did he or she go somewhere else or come here? Was it within the past year?
4. The last time this child received medical care for a bad cold or flu, did he or she go somewhere else or come here? Was it within the past year?

Answers are used to categorize each patient encounter into one of four broad categories of care: principal (PC) care, first-encounter (FE) care, specialized (SP) care, and consultative (CN) care. Defined in Table 1, the categories are listed in order beginning with the one thought most indicative of primary care. They are, therefore, listed in decreasing order of contribution to the index. Simply stated, a PC care encounter is a part of longitudinal care that includes both preventive services (question 3 above) and care for common acute illnesses (question 4 above) and adds the greatest weight to the index. Consultative care is a referral for a particular problem; because it is least indicative of primary care, it adds nothing to the numerator of the index. The classification algorithm is summarized in Table 2.

The four questions were asked by one of the two clinic registrars and answered by the adult accompanying each of 422 patients consecutively presenting for care to the PCC in the autumn of 1981. The responses were recorded on a log along with a number of demographic variables routinely collected at the time of registration.

Each encounter was categorized according to type. The visits of each type were summed and weighted according to the following formula to develop the primary care index¹³:

Category	Definition
Principal care (PC)	The patient receives ongoing nonreferral care for both preventive and acute day-to-day problems
First-encounter care (FE)	The patient is visiting the practice for the first time, but not by referral from an outside physician
Specialized care (SP)	The patient is receiving ongoing, nonreferral care for a particular problem or set of problems only
Consultative care (CN)	The patient is receiving care for a particular problem on referral by another physician

*Ordering of categories is from "most" to "least" indicative of primary care. From Weiner and Starfield.¹³

Care Category	Answers to Questions on Encounter Log			
	Referral	First Contact With Clinic	Last Checkup Here	Last Cold/Flu Care Here
Principal care (PC)	No	No	Yes or no†	Yes or no†
First-encounter care (FE)	No	Yes	No	No
Specialized care (SP)	No	No	No	No
Consultative care (CN)	Yes	Yes or no	Yes or no	Yes or no

*From Weiner and Starfield.¹³

†For an encounter to be classified as principal care, one of these two answers must be "yes."

$$\text{Index} = [(PC \times 1) + (FE \times 0.67) + (SP \times 0.33) + (CN \times 0)] / \text{Total No. of Encounters}$$

The index for the PCC was then compared with the analogous index for 20 Baltimore area private pediatric practices surveyed in late 1979.¹³ In addition, the percentages of encounters in each component of the index¹⁴ (ie, each care category) were compared, as were the percentages of patients reporting a checkup or cold/flu care within the previous year. The significance of observed differences was tested by χ^2 analyses of two-by-four and two-by-two tables.

The index was also calculated for the Harriet Lane Home (HLH), another Johns Hopkins hospital-based general pediatrics clinic. The HLH was staffed by faculty from the same division as the PCC and by pediatric house officers on block rotation, but was organized to be a "walk-in" clinic open for problem visits by patients with and without a regular source of care in the hospital or the community rather than to provide continuous primary care services. It had been observed that many parents who used community sources of medical care for "well-baby" visits brought their children to the HLH when the child was ill or had a particular type of problem. It was our hypothesis that the HLH was not providing a high level of primary care (that is, care that is not only accessible but comprehensive and longitudinal), and we believed that a measure useful in assessing pediatric practices should demonstrate that.

The questions previously used to classify

PCC encounters were addressed to adults consecutively bringing 211 patients for care at the HLH during specified half-days in the autumn of 1984 by a pediatric resident sitting at the registrar's desk. To provide a timely comparison, the index was once again calculated for the PCC using 162 consecutive patient encounters during exactly the same periods.

The χ^2 analyses of two-by-four tables were used to test the significance of differences noted between the HLH and the PCC and to assess the temporal stability of the encounter types in the PCC.

RESULTS

Of 422 adults questioned consecutively about the children they were bringing for care to the PCC in 1981, 20 could not or would not provide the answers to the questions. Of the remaining 402 encounters, 374 were indicative of PC care, 14 of FE care, 6 of SP care, and 8 of CN care.

In 1984, of 211 adults questioned about the children they were bringing for care to the HLH, 6 could not provide the necessary information. The classification of the remaining 205 was as follows: 105 were PC care, 48 were FE care, 43 were SP care, and 9 were CN care.

Of 162 adults questioned in 1984 about the child they were bringing to the PCC, 160 provided information. The en-

Table 3.—Number and Percent of Encounters in Categories of Care by Site and Time

	Time Period 1		Time Period 2	
	Baltimore Private Practices ¹⁴	Continuity Clinic (PCC)	Continuity Clinic (PCC)	Walk-In Clinic (HLH)
Year	1979	1981	1984	1984
No. of encounters	1254	402	160	205
Care category, No. (%)				
Principal care (PC)	1060 (84.5)	374 (93.0)	144 (90.0)	105 (51.0)
First-encounter care (FE)	94 (7.5)	14 (3.5)	8 (5.0)	48 (13.4)
Specialized care (SP)	37 (3.0)	6 (1.5)	0	43 (21.0)
Consultative care (CN)	63 (5.0)	8 (2.0)	8 (5.0)	9 (4.4)
Statistical values	$\chi^2 = 18.2$; $P < .001$	$\chi^2 = 6.6$; $P > .05$	$\chi^2 = 75$; $P < .001$	

Table 4.—Primary Care Index by Time and Practice Site

Site	Year	Primary Care Index
Private pediatric practitioners, mean	1979	79.9
Primary care clinic (PCC)	1981	95.8
Primary care clinic (PCC)	1984	93.4
Harriet Lane Home (HLH)	1984	73.9

Table 5.—Percent of Reported Care 'Here' in Past Year by Site

	Site and Year	
	Baltimore Private Practices (1979, N=1254) ¹⁴	Primary Care Clinic (1981, N=402)
Had checkup "here" in the past year, %	71.2	76.6 ($\chi^2 = 4.2$; $P < .05$)
Had cold/flu care "here" in the past year, %	60.2	68.7 ($\chi^2 = 9.4$; $P < .005$)

counters were classified as follows: PC care, 144; FE care, 8; SP care, 0; and CN care, 8.

The percentage of encounters fitting into each type of care for each of the sites and time periods is displayed in Table 3.

The PCC provided more PC care in 1981 than the sampled Baltimore area pediatricians in private practice in 1979 ($P < .001$) and, in 1984, more than the HLH ($P < .001$). The encounter distribution within the PCC in 1984 was not significantly different than in 1981 ($P > .05$).

The calculated index is displayed in Table 4 for each of the hospital clinics and times along with the mean index for the 20 private pediatric practitioners. The index for the PCC at both times was higher than the mean for Baltimore area pediatric practitioners (79.9).

Answers to the questions about re-

cency of care for PCC patients in 1981 were compared with answers for patients in the private practices. The percent reporting each type of care at the practice within a year is shown in Table 5. Compared with the patients attending sampled private pediatric practices in the Baltimore area in 1979, significantly more patients presenting for care at the PCC reported a "checkup" or cold/flu care at the practice in the past year.

COMMENT

Currently, standards for resident training in pediatric primary care, beyond continuity clinic time allotments specified by the Residency Review Committee, do not exist. This research was designed to evaluate one aspect of a particular primary care training site according to standards developed by the program staff. We believe a clinic organized to teach the practice of primary

care should provide primary care. Practitioners in other programs might find our method of characterizing the kind of care provided by our teaching practice useful.

The perhaps unexpected finding that the pediatric residents' continuity clinic at The Johns Hopkins Hospital had a high primary care index and provided more PC care than private pediatric practices in the area was encouraging, suggesting that the goal of providing a training site supportive of the attributes of primary care was being achieved in the two periods assessed. Particularly because the finding was unexpected, it is important to search for threats to the validity of the findings.

The primary care index is derived from parental reports of health service utilization as reflected in the answers to the questions posed on the patient log. Patients are known to be somewhat likely to offer what they perceive as the "socially desirable" or acquiescent response to questions about satisfaction with health care.¹⁶ The questions did not, however, address the question of satisfaction directly. Furthermore, we have no reason to believe that parents attending the PCC would be any more subject to this bias than would parents presenting to the HLH or, for that matter, to the area private practices. Likewise, there is no reason to suspect that one group of parents more than another would have difficulty accurately remembering the details of their children's health services. It is possible that our modest rephrasing of the questions to make them more appropriate to address to the parent of a patient made them easier to answer. This difference may help to explain why only 28 (3.5%) of 795 encounters in the PCC and HLH were not classifiable, while 11% of the 1409 encounters logged at the private pediatric practices could not be classified.¹⁴ Bias should be minimized by the fact that classifiable encounters were used as denominators for the calculations.

It is possible that the index is not the best measure of primary care for comparing pediatric practices. There is to date no generally accepted single measure of primary care, and currently used measures may produce divergent answers.³ The advantage of the index in

our situation was the availability of geographically relevant comparative data gathered at a not-too-distant time and the attractiveness of a previously validated measure of the health care process that could be easily applied.

An index score of 100 indicates that a physician or practice is providing only principal (or primary) care, while a score of 0 denotes a practice consisting entirely of CN care. While differences in scores were noted between the two Johns Hopkins clinics (Table 4), they were not as large as those previously reported between pediatrics and most specialties,¹⁸ and it is difficult to say what constitutes a "clinically" significant difference.

It is possible to mathematically compare the distributions of encounters among the four care categories for different service sites. Because a number of unmeasured changes may have influenced the process of health care provision in the Baltimore area over time, comparisons as close as possible in time deserve most credence. Therefore, only two-way statistical comparisons are made in Table 3: between the Baltimore area private practice results in 1979 and the PCC results obtained in the same season 2 years later; between data gathered simultaneously for PCC and HLH in 1984; and (only to assess stability of findings over years) between PCC data for 1981 and 1984.

Although the PCC in 1981 recorded a significantly larger proportion of encounters in the principal care category when compared with the private practice patient encounters, the similarity in percentages is certainly striking, adding weight to the conclusion that the PCC practice is representative of primary care if one considers private pediatric practice to be primary care. Also reassuring is the consistency in the index and the proportion of PC for the PCC in the two time periods. The fact that the index is lower and the proportion of PC care very different for the HLH when compared with the PCC suggests that the measures are sensitive enough to detect real differences in pediatric practices.

One possible source of bias in the encounter log data collection process is the circularity that only patients presenting to the practice are available for ques-

tioning; that is, fewer one-time patients who are going elsewhere for checkups and cold/flu care are being questioned. However, again, we have no reason to suspect that PCC patients would be more likely to leave the practice than patients of private practitioners. We know from other studies that the percentage of patients lost from the PCC practice over time is not large.¹⁶

Reports in the literature document how difficult it is for teaching practices to provide primary care. Breslau and Reeb⁶ studied provider continuity in their practice before and after they joined a medical school faculty and reorganized to become part of a university teaching clinic. Provider continuity for their sampled patients fell. Fletcher et al⁷ studied continuity and coordination of care for patients attending a hospital-based internal medicine teaching practice. Taking data from medical records, they found that 74.4% of visits made by the patients to the practice or elsewhere in the hospital were either "continuous" (to the principal provider) or "coordinated" (the principal provider knew of the visit to another provider and the second physician was aware of the primary provider). The authors were not satisfied with the percentage of visits to other providers that were coordinated by their definition, but did not present data by which coordination for the teaching practice patients could be compared with that afforded patients of private internists. Although our results are more encouraging, we did not study coordination or provider continuity.

Finally, analysis of recency of care reported by parents in the private practices in 1979 and the PCC in 1981 (Table 5) lends support to the assertion that the PCC practices primary care at a level similar to that of the private practices. The small differences noted in favor of the PCC might be explained by unmeasured differences in health care practices in the area over time, in the proportions of patients with chronic problems, or by the age profile of the two populations. Almost 12% of the patients in the private practices were age 15 years or older, compared with only about 4% of the PCC patients. In general, younger patients make more frequent, and therefore more recent, visits.

SUMMARY

We believe our results suggest that a residents' continuity clinic can, and the PCC did at the times data were collected, provide primary care. Our study does not address the quality of that care, but we believe we have completed one of several desirable steps to confirm that a hospital pediatric outpatient clinic can be an appropriate primary care training site. We suggest that the primary care index may be a useful tool in the ongoing evaluation of a continuity teaching practice.

We are grateful to Carolyn Session, Carol Ann Buckett, and Tracey Young for preparation of the manuscript, and to G. Nakajima and the PCC registrars for assistance in gathering data.

Growing up on a steady theophylline is an open-and-shut case

Sprinkled

Intact

Changing your patients from sprinkled to solid theophylline administration shouldn't mean changing their serum levels as well. With Slo-bid, you won't change a thing when your younger asthma patients are ready to switch to intact administration.

Slo-bid maintains steady theophylline levels when switching from sprinkled to solid administration¹

Switching from Slo-bid sprinkled to Slo-bid intact causes virtually no change in serum levels. Since the release system doesn't change, theophylline performance with both forms is identical. There's no need to restabilize your patients when they switch to taking capsules. In addition, capsules are the dosage form more patients prefer to take.²

Keep your patients' theophylline levels steady. Start and stay with Slo-bid. It's the perfect theophylline system for asthma patients to grow up with.

Slo-bid™

(theophylline, anhydrous)

50 mg, 75 mg, 100 mg, 125 mg, 200 mg, and 300 mg

Gyrocaps®

Timed-Release Capsules

BRIEF SUMMARY

DESCRIPTION: Slo-bid™ Gyrocaps® contain 50 mg, 75 mg, 100 mg, 125 mg, 200 mg, or 300 mg theophylline, anhydrous in the form of long-acting beads within a dye-free hard gelatin capsule and are intended for oral administration. Slo-bid Gyrocaps can be administered with a 12-hour dosing interval for a majority of patients and a 24-hour dosing interval for selected patients (see DOSAGE AND ADMINISTRATION section in full prescribing information for description of appropriate patient population).

INDICATIONS AND USAGE: For relief and/or prevention of symptoms from asthma and reversible bronchospasm associated with chronic bronchitis and emphysema.

CONTRAINDICATIONS: Slo-bid is contraindicated in individuals who have shown hypersensitivity to any of the components of this product. It is also contraindicated in patients with active peptic ulcer disease and in individuals with underlying seizure disorders (unless receiving appropriate anticonvulsant medication).

WARNINGS: Serum levels above 20 µg/mL are rarely found after appropriate administration of the recommended doses. However, in individuals in whom theophylline plasma clearance is reduced for any reason, even conventional doses may result in increased serum levels and potential toxicity. Reduced theophylline clearance has been documented in the following readily identifiable groups: 1) patients with impaired renal or liver function; 2) patients over 55 years of age, particularly males and those with chronic lung disease; 3) those with cardiac failure from any cause; 4) patients taking oral contraceptives; 5) neonates and infants under 1 year of age; and 6) those patients taking certain drugs (see PRECAUTIONS, Drug Interactions). Frequently, such patients have markedly prolonged theophylline serum levels following discontinuation of the drug.

Reduction of dosage and laboratory monitoring is especially appropriate in the above individuals.

Serious side effects such as ventricular arrhythmias, convulsions, or even death may appear as the first sign of toxicity without any previous warning. Less serious signs of theophylline toxicity (i.e., nausea and restlessness) may occur frequently when initiating therapy but are usually transient; when such signs are persistent during maintenance therapy, they are often associated with serum concentrations above 20 µg/mL. Stated differently, *serious toxicity is not reliably preceded by less severe side effects.* A serum concentration measurement is the only reliable method of identifying a potential for life-threatening toxicity.

Many patients who require theophylline exhibit tachycardia due to their underlying disease process, so the cause/effect relationship to elevated serum theophylline concentrations may not be appreciated.

Theophylline products may cause dysrhythmia and/or worsen preexisting arrhythmias and any significant change in rate and/or rhythm warrants monitoring and further investigation.

Studies in laboratory animals (minipigs, rodents, and dogs) recorded the occurrence of cardiac arrhythmias and sudden death (with histologic evidence of myocardial necrosis) when beta agonists and methylxanthines were administered concurrently. The significance of these findings when applied to humans is currently unknown.

PRECAUTIONS: **General:** On the average, theophylline half-life is shorter in cigarette and marijuana smokers than in nonsmokers, but smokers can have half-lives as long as nonsmokers. Theophylline should not be administered concurrently with other xanthine preparations. Use with caution in patients with hypoxemia, hypertension or with a history of peptic ulcer. Theophylline may occasionally act as a local irritant to the GI tract, although GI symptoms are more commonly centrally mediated and associated with serum drug concentrations over 20 µg/mL.

Information for Patients:

The physician should reinforce the importance of taking only the prescribed dose at the prescribed time intervals. The patient should alert the physician if symptoms occur repeatedly especially near the end of a dosing interval. When prescribing administration by the sprinkle method, details of the proper technique should be explained to the patient.

Laboratory Test: Serum levels should be monitored periodically to determine the theophylline levels associated with observed clinical response and to identify the potential for toxicity. For such measurements, the serum sample should be obtained at the time of peak concentration, approximately 5-9 hours after the morning dose. It is important that the patient has not missed or taken additional doses during the previous 48 hours and that dosing intervals have been reasonably equally spaced.

DOSE ADJUSTMENT BASED ON SERUM THEOPHYLLINE MEASUREMENTS WHEN THESE INSTRUCTIONS HAVE NOT BEEN FOLLOWED MAY RESULT IN RECOMMENDATIONS THAT PRESENT RISK OF TOXICITY TO THE PATIENT.

Drug Interactions:

Drug-Drug: Toxic synergism with ephedrine has been documented and may occur with some other sympathomimetic bronchodilators. In addition, the following drug interactions have been demonstrated:

Theophylline with:	Increased serum theophylline levels
Allopurinol (high dose)	Increased serum theophylline levels
Cimetidine	Increased serum theophylline levels
Erythromycin, Troleandomycin	Increased renal excretion of lithium
Lithium carbonate	Increased serum theophylline levels
Oral contraceptives	Decreased theophylline and phenytoin serum levels
Phenytoin	Decreased serum theophylline levels
Rifampin	

Drug-Food: Taking Slo-bid immediately after a high-fat content meal such as 8 ounces whole milk, 2 fried eggs, 2 strips bacon, one bran muffin with butter, 2 ounces hash brown potatoes (about 789 calories, including approximately 49 gm of fat) may result in a decrease in the rate of absorption, but with no significant difference in the extent of absorption (see CLINICAL PHARMACOLOGY Pharmacokinetics). The influence of the type and amount of other foods, as well as the time interval between drug and food, has not been studied.

Drug/Laboratory Test Interactions: Currently available analytic methods, including high-pressure liquid chromatography and immunoassay techniques, for measuring serum theophylline levels are specific. Metabolites and other drugs generally do not affect the results. Other new analytic methods are also now in use. The physician should be aware of the laboratory method used and whether other drugs will interfere with the assay for theophylline.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies have not been performed with theophylline.

Chromosome-breaking activity was detected in human cell cultures at concentrations of theophylline up to 50 times the therapeutic serum concentrations in humans. Theophylline was not mutagenic in the dominant lethal assay in male mice given theophylline intraperitoneally in doses up to 30 times the maximum daily human oral dose.

Studies to determine the effect on fertility have not been performed with theophylline.

Pregnancy: Pregnancy Category C—Animal reproduction studies have not been conducted with theophylline. It is also not known whether theophylline can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Theophylline should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Theophylline is distributed into breast milk and may cause irritability or other signs of toxicity in nursing infants. Because of the potential for serious adverse reactions in nursing infants from theophylline, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use:

Safety and effectiveness of Slo-bid Gyrocaps administered:

1. Every 24 hours in children under 12 years of age, have not been established.
2. Every 12 hours in children under 6 years of age, have not been established.

ADVERSE REACTIONS: The following adverse reactions have been observed, but there has not been enough systematic collection of data to support an estimate of their frequency. The most consistent adverse reactions are usually due to overdosage.

Gastrointestinal: nausea, vomiting, epigastric pain, hematemesis, diarrhea.

Central Nervous System: headaches, irritability, restlessness, insomnia, reflex hyperexcitability, muscle twitching, clonic and tonic generalized convulsions.

Cardiovascular: palpitation, tachycardia, extrasystoles, flushing, hypotension, circulatory failure, ventricular arrhythmias.

Respiratory: tachypnea

Renal: potentiation of diuresis.

Other: alopecia, hyperglycemia, inappropriate ADH syndrome, rash.

CAUTION: Federal (U.S.A.) law prohibits dispensing without prescription. Keep this and all medications out of the reach of children.

HOW SUPPLIED: Slo-bid Gyrocaps are identified as follows:

- 50 mg—Clear (cap) and opaque white (body) capsule with 50 printed in red
- 75 mg—Opaque white (cap) and clear (body) capsule with 75 printed in red
- 100 mg—Clear capsule with 100 printed in red
- 125 mg—Opaque white (cap) and opaque white (body) capsule with 125 printed in red
- 200 mg—Opaque white (cap) and clear (body) capsule with 200 printed in red
- 300 mg—Opaque white capsule with 300 printed in red

Slo-bid Gyrocaps 50 mg are available in bottles of 100 (NDC 0075-0057-00), bottles of 1000 (NDC 0075-0057-99) and in unit dose 10 x 10 (NDC 0075-0057-62). Slo-bid Gyrocaps 75 mg are available in bottles of 100 (NDC 0075-1075-00), bottles of 1000 (NDC 0075-1075-99) and in unit dose 10 x 10 (NDC 0075-0057-62). Slo-bid Gyrocaps 100 mg are available in bottles of 100 (NDC 0075-0100-00), bottles of 1000 (NDC 0075-0100-99) and in unit dose 10 x 10 (NDC 0075-0100-62). Slo-bid Gyrocaps 125 mg are available in bottles of 100 (NDC 0075-1125-00), bottles of 1000 (NDC 0075-1125-99) and in unit dose 10 x 10 (NDC 0075-1125-62). Slo-bid Gyrocaps 200 mg are available in bottles of 100 (NDC 0075-0200-00), bottles of 1000 (NDC 0075-0200-99) and in unit dose 10 x 10 (NDC 0075-0200-62), and Slo-bid Gyrocaps 300 mg are available in bottles of 100 (NDC 0075-0300-00), bottles of 1000 (NDC 0075-0300-99) and in unit dose 10 x 10 (NDC 0075-0300-62), and are manufactured by

Late Sudden Unexpected Deaths in Hospitalized Infants With Bronchopulmonary Dysplasia

Steven H. Abman, MD; Molly F. Burchell, MD; Michael S. Schaffer, MD; Adam A. Rosenberg, MD

• To determine the relative contribution of sudden death as a cause of late inpatient mortality in newborns after prolonged mechanical ventilation, we reviewed the charts of 348 patients who received ventilation assistance and who were admitted to the neonatal intensive care unit during a 26-month period. The overall mortality rate for these patients was 25%, with 88% (77/88) of these deaths occurring within 30 days of birth. Eleven infants died after more than 60 days of mechanical ventilation. Seven of these late deaths were sudden, unexpected in-hospital deaths. Sudden deaths occurred at a mean (uncorrected) age of 12 months (range, 4 to 27 months), during periods when infants appeared to be stable or clinically improving, were unrelated to recent respiratory exacerbations, and occurred despite prompt resuscitative efforts. Four infants still required mechanical ventilation, and 4 had tracheostomies at the time of death. All of the infants had chronic hypercarbia (>50 mm Hg) and an elevated serum bicarbonate level (>30 mmol/L), but not hyponatremia, hypochloremia (<80 mmol/L), or alkalemia. Left and right ventricular hypertrophy, multiple drug therapy, recurrent cyanotic episodes, and frequent unexplained fevers were common. In comparison with 17 bronchopulmonary dysplasia survivors who required longer than 60 days of ventilation therapy, the late deaths group more frequently had left ventricular hypertrophy and received prolonged combination theophylline anhydrous and β -adrenergic agonist therapy. We report that sudden death can occur in infants with severe bronchopulmonary dysplasia despite in-hospital cardiopulmonary monitoring and the rapid institution of cardiopulmonary resuscitation, and is a significant cause of late mortality in infants who receive ventilation therapy for longer than 2 months.

Bronchopulmonary dysplasia (BPD) represents a spectrum of persistent cardiopulmonary abnormalities following oxygen and ventilator therapy for neonatal respiratory failure.^{1,2} Although the clinical course for most infants with BPD is characterized by steady improvement in growth, lung function, and oxygen requirement, a significant proportion of neonatal intensive care unit (NICU) survivors with BPD have major morbidity and mortality.^{2,4} Causes of mortality in infants with BPD include progressive cardiorespiratory failure, sepsis, pneumonia, and sudden death.^{2,7-16} Although sudden deaths have been previously reported in infants with BPD, causes and associated risk factors are unknown.^{10,12,15} In addition, previous reports have described sudden death exclusively in outpatient populations of infants with BPD.^{10,13,15} We have observed late sudden deaths in hospitalized children with BPD, who were clinically stable or improving in the period preceding death. To determine the relative contribution of these sudden, unexpected deaths to the late mortality of severe BPD and to initiate investigation into potential risk factors, we reviewed the clinical courses of children with late deaths following long-term ventilator support in the NICU.

PATIENTS AND METHODS

We reviewed the hospital records of all ventilated newborns admitted to the NICU at the University of Colorado, Denver, between June 1984 and August 1986. By chart review, we determined the period of death as less than 30 days of age, between 30 and 60 days, between 60 and 90 days, or 91 days or more. Records of infants dying after more than 60 days of mechanical support were analyzed for details of their clinical course. The following data were recorded: birth weight, gestational age, associated perinatal problems, primary diagnosis when admitted to the NICU, duration of mechanical ventilation, and associated clinical problems (eg, apnea, recurrent cyanotic episodes, frequent fevers, structural airway abnormalities, cardiac hypertrophy, systemic hypertension,

intraventricular hemorrhage, hydrocephalus, and seizures). The types and duration of medications used, serum electrolyte levels, blood gas tensions, and outcome were also recorded.

Recurrent cyanotic episodes were defined as frequent episodes of sudden onset of severe cyanosis, with or without subsequent bradycardia and recognized as clinically significant, as reflected by such interventions as hand-bagging, calming, sedation, or the administration of β -adrenergic medications. Recurrent fever was defined as sustained or frequent elevations of temperature above 38.5°C without apparent source. Systemic hypertension was defined as persistent systolic blood pressure above 113 mm Hg on repeated assessments obtained while the patient was at rest.¹⁷ Serum electrolyte disturbances were defined as persistent abnormalities throughout the hospital course or within 2 weeks of death. Abnormal measurements included values of serum sodium less than 130 mmol/L, serum potassium less than 3.5 mmol/L, serum chloride less than 80 mmol/L, serum bicarbonate greater than 30 mmol/L, and PaCO_2 over 50 mm Hg. Growth parameters were assessed according to percentile for corrected age, using National Center for Health Statistics standards. Echocardiographic and electrocardiographic (ECG) measurements were compared with age-appropriate normal values.^{18,19}

Clinical management was determined by the NICU and pediatric special care unit medical teams managing the individual patients. Despite some variations in therapeutic approaches, respiratory care included maintaining oxygen saturations or transcutaneous PCO_2 consistently above 92% to 94% or 55 mm Hg while the infant was awake, feeding, or asleep as previously described.⁴ Arterial PCO_2 was allowed to remain between 50 and 65 mm Hg as long as pH was maintained in the normal range (7.35 to 7.45). Medications often used in the management of these children with chronic lung disease included diuretics (furosemide or a combination of hydrochlorothiazide and spironolactone [Aldactone]), β -adrenergic nebulizers, theophylline, and corticosteroids. Other aspects of clinical care for these infants was similar to those recently described by Schreiner et al.¹²

Comparisons of the clinical and laboratory courses were made between a control group of infants with severe BPD who required

longer than 60 days of mechanical ventilation who survived (group 1) and the infants with BPD who died suddenly (group 2). Twenty-three of the 34 infants with BPD who received ventilatory assistance for longer than 60 days survived. Of these, 4 patients required long-term ventilator support to treat severe tracheomalacia (3 children) or an upper airway obstruction due to a massive encephalocele (1 infant). One infant with severe congestive heart failure due to congenital heart disease was ventilated. Because these children had minimal clinical and radiologic signs of lung parenchymal disease, they were excluded from further comparisons with the infants with BPD. A sixth infant had chronic lung disease following long-term ventilation but was born with a severe hypertrophic cardiomyopathy and was therefore excluded. The hospital records of the remaining 17 infants with clinical BPD and parenchymal disease (group 1) were reviewed as described earlier.

Statistical analysis was performed by Student's *t* test and Fisher's Exact Test with a *P* < .05 considered significant.

RESULTS

We identified 348 infants who required mechanical ventilation therapy in our NICU during this 26-month period. As shown in Table 1, 88 infants died (25.3% mortality), with 77 deaths (88%) occurring in infants ventilated for less than 30 days. All of the infants who were ventilated for 30 to 60 days survived. Of 34 infants ventilated beyond 60 days, 11 died (32%), with all of these deaths occurring beyond 90 days. Seven of these deaths were sudden and unexpected. Causes of death in the 4 other infants were perforated duodenal ulcer during long-term corticosteroid therapy, progressive respiratory failure in a 24-week preterm infant and in an infant with congenital diaphragmatic hernia, and severe cardiac failure in an infant with cutis laxa and an aneurysm of the ascending aorta.

Table 2 gives some of the clinical characteristics of the seven infants with BPD who died suddenly. Mean birth weight and gestational age were 1184 g (range, 790 to 2000 g) and 28 weeks (range, 26 to 33 weeks), respectively. The primary diagnosis when admitted to the NICU was hyaline membrane disease for all of the infants. Only one had an intraventricular hemorrhage of grade 2 or above. Mean age at the time of death was 12.3 months (uncorrected),

ranging between 4 and 27 months. At the time of death, four infants (57%) still required mechanical ventilation therapy and four had tracheostomies. Five of the seven infants had at least one bronchoscopy, with abnormalities reported in three patients. These included tracheomalacia (two infants), subglottic stenosis (one infant), and bronchial stenosis (two infants). Each child was clinically stable or steadily improving preceding sudden death. One infant died within days of a date set for home discharge. None had evidence of acute respiratory tract infection, or required an increase in the frequency or dosage of diuretic or bronchodilator therapy in the week preceding death. None of the infants had elevated theophylline levels (>20 mg/L). Although six infants had

Paco₂ above 50 mm Hg and all infants had serum bicarbonate levels greater than 30 mmol/L, none had significant hypochloremia (<80 mmol/L). All seven infants had left ventricular hypertrophy (LVH). The diagnosis of LVH was made by ECG and echocardiogram in two patients, echocardiogram only (with normal ECG studies) in four infants, and at autopsy only in one child who had several normal ECG studies without an echocardiogram. Late echocardiographic studies were performed in six infants, at a mean age of 18.6 months. All six children had evidence of LVH, as determined by increased left ventricular posterior wall and interventricular septal thickness. Left ventricular internal diameter was decreased in four of six patients. In addition, right ventricular

systolic time interval was elevated in five of six infants.

In each case, at the time of death, a sudden onset of bradycardia was noted, which persisted and progressed to asystole and death, despite the rapid institution of cardiopulmonary resuscitation. None of the patients had evidence of plugged endotracheal or tracheostomy tubes, or improved with reintubation. Death ensued despite ventilation by hand-bagging with 100% fraction of inspired oxygen concentration chest compression and the administration of cardiotonic medications. Autopsies were obtained in four infants, but failed to document a specific cause of death. Postmortem bacterial or viral cultures failed to demonstrate bacteremia, pneumonia, or other infections. Autopsy findings included biventricular hypertrophy with mild intercellular edema without histologic evidence of acute myocardial infarction (four infants). One infant had endocardial fibroelastosis. Old myocardial infarction or inflammatory infiltrates were not found. The cardiac conduction system was not examined. Mild pulmonary hypertensive changes, consisting predominantly of smooth-muscle thickening, were found in each case. Findings diagnostic of pneumonia or aspiration were absent. Acute hemorrhage, thrombosis, or recent ischemic brain injury was not noted. Chronic neuropathologic lesions included periventricular leukomalacia (two infants) and severe micropolygyria with scaphocephaly and hydrocephalus ex vacuo (one infant).

To identify clinical risk factors potentially associated with these deaths, we compared the clinical and laboratory findings of infants with BPD who died suddenly (group 2, Table 2) with a control group of infants with BPD who survived after prolonged ventilation therapy (>2 months, group 1). In comparison with control infants, the sudden death group had significantly greater gestational age ($P<.01$) and birth weight ($P<.02$) and required longer ventilator support ($P<.02$). In addition, the presence of LVH, recurrent cyanotic episodes, tracheostomy, and long-term combination drug therapy of theophylline with β -nebulizer were more frequent in group 2 infants. Persistent electrolyte abnormalities, including low

serum concentrations of sodium, potassium, and chloride, or alkalemia, were infrequently found in either group. The incidence of nephrocalcinosis and grade 2 or greater intraventricular hemorrhage were similar between groups.

To further examine clinical factors that may be associated with late sudden deaths, we also compared the sudden death group with the five surviving infants with BPD in group 1 who were ventilated for more than 90 days. These five infants were more comparable with the group 2 infants in terms of the severity of their hospital courses. No significant differences were found between these groups in gestational age (26.6 ± 2.0 weeks for survivors [mean \pm SD]), birth weight (848 ± 305 g [mean \pm SD]), weight below the third percentile (three of five patients), systemic hypertension (one of five patients), right ventricular hypertrophy (three of five patients), or tracheostomy (two of five patients). The frequency of recurrent cyanotic episodes and frequent unexplained fevers were similar between groups. However, the infants with BPD who died suddenly had a significantly greater incidence of LVH (one of five vs seven of seven patients; $P<.02$) and were more frequently treated with the combination of theophylline and β -adrenergic medications (one of five vs six of seven patients; $P<.05$). Long-term use of theophylline, β -agonist or diuretic therapies alone, or the combination of diuretic with either theophylline or β -agonist were not different among the groups. All patients from both groups received diuretic therapy.

COMMENT

We report a previously unpublished observation that infants with BPD can die suddenly and unexpectedly as inpatients, despite cardiorespiratory monitoring and the rapid initiation of aggressive cardiopulmonary resuscitation. Sudden unexpected deaths occurred in 7 of the 11 late deaths in infants with severe BPD who had been treated with mechanical ventilation for more than 60 days. These in-hospital deaths occurred despite stable or improving clinical status, without apparent acute respiratory exacerbation, and despite the rapid initiation of resuscitation efforts. Death was preceded by the acute onset of bra-

dycardia, leading to asystole that was unresponsive to cardiopulmonary resuscitation, including the use of cardiotonic medications. These sudden deaths occurred in infants with BPD who had common manifestations of severe disease, including prolonged mechanical ventilator support, multiple drug therapy, persistent LVH and right ventricular hypertrophy, and prolonged hospitalization. In addition, recurrent cyanotic "spells" and multiple episodes of unexplained fevers were common. Despite the presence of these chronic clinical problems, these sudden deaths are of undetermined etiology and occurred when the patients appeared clinically stable. When compared with survivors of long-term mechanical ventilation therapy following NICU admission during the same period, the sudden death group more frequently had LVH and were more often receiving concomitant diuretic, β -adrenergic, and theophylline therapy. Study groups, however, were small, and the true incidence of LVH may be underestimated in the survivors.

Previous studies that have addressed inpatient deaths in older infants with severe BPD have not reported sudden death.^{11,12,14,16} Progressive respiratory failure, heart failure, airway accidents, sepsis, and infection were most commonly found. In contrast to one study of late mortality in BPD,¹¹ we did not find an association with chloride deficiency or alkalemia with these deaths. As was the case in a recent report of infants with BPD dying following prolonged ventilation therapy, we observed that recurrent cyanotic episodes are common in the infants with BPD who died suddenly.¹⁶ However, these spells are also frequently present in many survivors of severe BPD.

An increased incidence of sudden deaths in infants with chronic lung disease following discharge from the NICU has been previously described.^{10,13,16} Werthammer et al¹⁰ reported that 11% of the infants with BPD who died of "sudden infant death syndrome" (SIDS) following discharge from the NICU. In comparison, the incidence of SIDS in preterm infants without BPD was 1.5%. However, considering the cardiopulmonary abnormalities associated with BPD, it seems inappro-

priate to classify unexplained sudden deaths in this population as SIDS.²⁰ Two other studies found that sudden deaths accounted for 10% and 28% of late deaths following discharge from the NICU.^{13,15} In these reports, however, sufficient clinical data are not provided to assess the presence or severity of cardiopulmonary disease in the sudden deaths. Most of the reported sudden deaths were in young outpatients, younger than 4 months of age. In contrast, we have previously noted that sudden deaths in infants with BPD who were enrolled in our home oxygen follow-up (outpatient) program are rare.^{4,21} Reports of sudden deaths in outpatient infants with BPD have led to the suggestion that aggressive monitoring, close follow-up, and early cardiopulmonary resuscitation can prevent these deaths.^{22,23} The cases in our report suggest that sudden deaths in BPD can occur despite monitoring and the early intervention. In addition, these findings imply that mechanisms, in addition to abnormal control of breathing or plugged tracheostomy tubes, may contribute to sudden death in BPD.

Left ventricular hypertrophy was present in each of the infants with BPD who died suddenly. Whether the development or presence of persistent LVH in infants with BPD is a risk factor or simply parallels more severe disease warrants prospective study. Left ventricular hypertrophy has been previously reported in infants with BPD, but its cause and potential contribution to the late mortality of BPD, including sudden death, are unclear.⁹ A high incidence of LVH (14 of 28 cases) was also found at autopsy in a previous study of late BPD deaths,⁸ but was rarely found in previous clinical studies of late mortality in infants with BPD.^{11,16} Of clinical importance is the finding in this study that five of the seven infants with LVH determined by echocardiogram and autopsy had serial ECG studies without evidence of LVH, suggesting that the incidence of LVH may be underreported if only ECG assessments are performed at follow-up. The etiology of LVH in infants with BPD is unknown. Although systemic hypertension can be associated with LVH in infants with BPD,²⁴ many infants with BPD who have LVH do not have recognized ele-

vations of blood pressure. Other potential causes of LVH include the effects of ventricular interdependence,²⁵ repeated episodes of ischemic myocardial injury,^{14,26,27} or myocardial toxicity from aggressive bronchodilator or corticosteroid therapy. Chronic adrenergic stimulation from aggressive diuretic use with volume contraction, hypercapnia, stress, or diminished pulmonary vascular clearance or net production of norepinephrine are additional possibilities.²⁸⁻³²

Although acute respiratory infection is a possible contributing factor to death, the lack of prodromal signs in these sudden death cases and the negative results of postmortem bacterial and viral cultures make it less likely as a cause of death in these cases. Although it has been speculated that late sudden deaths may reflect abnormalities in the control of breathing or airway obstruction,¹⁰ the inpatient deaths reported herein suggest that alternative mechanisms may also be important. Acute airway obstruction seems an unlikely cause because of the rapid resuscitation response, which included assessment for airway obstruction, and the immediate initiation of ventilation. However, it is possible that acute hypoxia, triggered by transient airway obstruction, apnea, severe gastroesophageal reflux, or other events, can precipitate a dysrhythmia, which proves fatal, despite resolution of the hypoxia.³³ In addition, myocardial hypertrophy increases the risk for sudden death and dysrhythmias, especially secondary to elevations of catecholamine levels.^{34,35} Dramatic surges of plasma catecholamine levels can occur during cyanotic episodes in infants with BPD.³⁰ Hypoxia, hypokalemia, viral infection, and other factors may also potentially aggravate the risk for dysrhythmias in this clinical setting.³⁴ Whether methylxanthines and adrenergic agonists used to treat BPD contribute to an increased risk of sudden death is unknown. It has been speculated that the recently recognized rise in asthma deaths may in part be related to increasing use of combined theophylline and β -adrenergic agonists.³⁶

Although neurologic abnormalities could potentially contribute to sudden death, no evidence of an acute catastrophic event (eg, acute hemorrhagic

or ischemic brain injuries) was found. Although chronic neuropathologic lesions, including periventricular leukomalacia and severe micropolygyria with scaphocephaly and hydrocephalus ex vacuo, were observed, the exact mechanisms by which these lesions could contribute to the sudden demise of these hospitalized patients with BPD is unclear. However, the number of autopsies were limited to four children, and future investigations of the potential role of neurologic abnormalities to sudden death are needed before firm conclusions can be made.

CONCLUSION

We conclude that sudden unexpected late deaths contribute significantly to late mortality in older infants with severe BPD following prolonged mechanical ventilation. That mortality is high in sick children with BPD who require prolonged ventilation is not surprising. However, although these infants died with BPD, the actual cause of death is unknown, and mechanisms underlying the sudden nature of their death, especially while appearing to be clinically stable or improving, are unclear. Whether cardiac hypertrophy or our current use of "polypharmacy"³⁹ in the management of severe BPD contributes to sudden death or related clinical morbidity remains to be determined. Although this study is limited by its retrospective nature, it describes a substantial clinical problem and will, it is hoped, serve to stimulate future prospective studies of factors that contribute to late mortality and sudden death in infants with severe BPD.

This investigation was supported in part by grant HL01932-01 (Dr Abman) from the National Institutes of Health, Bethesda, Md.

Height and Weight Following Lead Poisoning in Childhood

Henrietta K. Sachs, MD, Donald I. Moel, MD

• The effect of lead on growth was examined in 104 lead-poisoned subjects (Pb-B [blood lead concentration], 4.82 to 22.73 $\mu\text{mol/L}$) and 27 sib-controls (Pb-B, 0.48 to 1.88 $\mu\text{mol/L}$). Blood lead concentration, height, and weight are reported for 1974 (the year of their first posttreatment recall for evaluation) and for 1985 (the year of their sixth recall). In 1974, when their mean age was 8 years and their mean Pb-B was 1.68 $\mu\text{mol/L}$, about 70% of the patients and sib-controls were in the 50th to 95th percentiles for height and weight. In 1985, when their mean age was 18 years and all Pb-Bs were less than 1.20 $\mu\text{mol/L}$, height and weight percentiles were similar to those of 1974. Lead did not seem to affect the genetic predisposition for height attainment, at high or low blood lead levels. (AJDC. 1989;143:820-822)

Blood lead concentration (Pb-B) at low levels has been cited as causing several disparate conditions in children, among them, growth retardation.¹ To test the accuracy of this observation, we examined the height and weight data of lead-poisoned patients (Pb-B, 4.82 to 22.73 $\mu\text{mol/L}$) and a sibling cohort (Pb-B, 0.48 to 1.88 $\mu\text{mol/L}$) whom we have followed up for 15 to 20 years. The first recall was in 1974, 2 to 6 years after the patient-sib was treated; the sixth recall was in 1985, when all subjects but one were adolescents or adults.

SUBJECTS AND METHODS

Patients and sib-controls have been described.² They were found through a broad, urban screening program. Patients, who were 16 to 55 months of age when lead poisoning was diagnosed, were treated with British anti-Lewisite and edetic acid, or edetic acid alone, then with penicillamine until Pb-B fell to 2.41 $\mu\text{mol/L}$. Blood lead was then permit-

ted to fall spontaneously to normal adult levels, a process that often extended beyond pubescence.³ A report describing the patients' present psychosocial function is being prepared and will not be presented herein. Sib-controls did not have pica or a Pb-B above 1.88 $\mu\text{mol/L}$, the requisite blood level for evaluation between 1966 and 1972, when all subjects were screened, and the patient cohort was treated.

Data were obtained from 104 patients and 27 sib-controls in 1974, and from 77 patients and 21 sib-controls in 1985. Height and weight measurements were tabulated according to percentiles of the National Center for Health Statistics.⁴ Subjects were placed in the following four categories, based on pretreatment Pb-B: 9.62 $\mu\text{mol/L}$ or more; 7.23 to 9.60 $\mu\text{mol/L}$; 4.82 to 7.19 $\mu\text{mol/L}$; and sib-controls, 1.88 $\mu\text{mol/L}$ or less. The number of measurements in or above the 50th percentile for height (Ht%) and for weight (Wt%) for the 2 recall years are given in Table 1.

RESULTS

Initial Pb-B Was Not a Factor Contributing to Growth Retardation

In 1974, 73 patients had Pb-Bs of 1.44 to 2.75 $\mu\text{mol/L}$ and 30 had Pb-Bs of 0.62 to 1.88 $\mu\text{mol/L}$; 51 (70%) of the higher lead group and 23 (77%) of the lower group were in or above the 50th Ht% (Table 1). By 1985, when almost all subjects had completed the adolescent growth spurt, and all Pb-Bs were less than 1.30 $\mu\text{mol/L}$, 53 (69%) of the 77 patients were in or above the 50th Ht%, and 65 (84%) were in or above the 50th Wt% (Table 1).

Symptomatic Lead Poisoning Was Not a Factor

Twenty of the 32 symptomatic patients were in or above the 50th Ht% at both recalls. The three children who had at least one seizure were in the 3rd, 50th, and 95th Ht%, respectively.

Age at Onset Was Not a Factor

In 1974, 44 patients were between 3 and 6 years of age, and closest in time to their episode of lead poisoning; 28 (64%) of the 44 were in or above the 50th Ht% and Wt%. Ten of the 13 youngest patients (77%), aged 3 and 4 years, were in or above the 50th Ht%, compared with 18 (58%) of 31 patients, aged 5 and 6 years (Table 2).

Ethnicity Was a Determinant of Height

All subjects were black or Hispanic. Seven of the eight Hispanic patients were in the first to the 25th Ht%, and six were in the first to the 25th Wt%. Eight of an additional nine Hispanics whose Pb-Bs were below 4.82 $\mu\text{mol/L}$ and two of their three sib-controls were below the 35th Ht%. In 1974, the eight Hispanics (Pb-B, $\geq 4.82 \mu\text{mol/L}$) had a mean Ht% of 16, and a mean Wt% of 38. The six Hispanics available in 1985 had a mean Ht% of 21 and a mean Wt% of 37. In both follow-up years, 20% of the patients, including most of the Hispanics, were in or below the 16th Ht%, and 28% (none of them Hispanics) were in or above the 84th Ht%.

Heredity Was the Determinant of Height

In 1974, 27 patients provided a sib-control cohort. Concordance between siblings for height percentiles was present in 15 pairs (56%); 4 patients were in a higher percentile than their sibs (15%), and 8 were in a lower one (30%). Concordance for weight percentiles was similar in 1985, as were the results (Table 3). To eliminate the role of chance in concordance, sets were rearranged so that patient 1 was paired to sib-control 2, etc, and patient 27 to sib-control 1. Only 8 patients (30%) exhibited concordance for height; 10 patients were taller and 10

patients were shorter than the nonrelated sib-control.

COMMENT

There are few published observations on the association of growth with Pb-B. Absence of effect may be surmised from lack of reference to interference with development in environmentally exposed children^{5,6} examined for medical and neurological lesions.

Reports of impaired growth have been derived from data collected for other objectives. While investigating dietary intake, Mooty et al⁷ obtained a Ht% mean of 32 for subjects with a Pb-B of 2.41 to 3.84 $\mu\text{mol/L}$ and a Ht% mean

of 41 for controls with a Pb-B of 0.48 to 1.20 $\mu\text{mol/L}$. Our results would also have been skewed toward short stature if expressed as a mean, and the fact obscured that the majority of our patients were in or above the 50th Ht%. For example, the mean Ht% of patients with a Pb-B of 7.23 to 9.60 $\mu\text{mol/L}$ was 45, yet 61% were in the 50th to 95th Ht%.

Schwartz et al⁸ deduced from their analysis of National Health and Nutrition Examination Survey⁹ data that stature is inversely correlated to Pb-B, and that Pb-Bs of 0.24 to 1.68 $\mu\text{mol/L}$ are statistically significant predictors of children's height ($P < .0001$), weight

($P < .001$), and chest circumference ($P < .026$). Since the National Health and Nutrition Examination Survey estimated that only 4% of children have Pb-Bs above 1.44 $\mu\text{mol/L}$, can chance lead tests made between 6 months and 5 years of age govern the order of height of 96% of the population? Their analysis refutes the accepted genetic relationship between parents' and children's heights.^{10,11}

CONCLUSION

Our patients not only experienced severe lead poisoning but twice ran the low level gamut, as they ascended from, then descended to, the normal range for

Pb-B. Thus they are uniquely qualified for an inquiry into sequelae of all Pb-Bs. With respect to Ht% and Wt%, about 70% placed in the 50th to 95th percentiles, from childhood through adoles-

cence, skewing the normal distribution of Ht% and Wt% to the right. Furthermore, during years of observation, they maintained a consistent similarity to their unaffected sibs in those param-

ters. Blood lead at any concentration did not seem to affect growth or alter the genetic predisposition for eventual adult height.

Manganese Absorption From Human Milk, Cow's Milk, and Infant Formulas in Humans

Lena Davidsson, BSc; Åke Cederblad, MSc; Bo Lönnerdal, PhD; Brittmarie Sandström, PhD

• Manganese absorption from human milk, cow's milk, and infant formulas was studied in humans by using extrinsic labeling of the diets with manganese 54 or manganese 52 and whole-body retention measurements. The fractional manganese absorption from human milk ($8.2\% \pm 2.9\%$) was significantly different when compared with cow's milk ($2.4\% \pm 1.7\%$), soy formula ($0.7\% \pm 0.2\%$), and whey-preponderant cow's milk formula with 12 mg/L of iron ($1.7\% \pm 1.0\%$) and without iron fortification (2 mg/L of iron) ($3.1\% \pm 2.8\%$), while no significant difference was observed between a whey-preponderant cow's milk formula with 7 mg/L of iron ($5.9\% \pm 4.8\%$) and human milk. The total amount of absorbed manganese was significantly higher from the non-iron-fortified cow's milk formula (2 mg/L of iron) as compared with human milk, while no significant differences were observed for the other milks and formulas. (AJDC. 1989;143:823-827)

There has been little focus on the role of manganese in infant nutrition, and manganese nutrition in the neonatal period is poorly understood, partly because of the lack of information on manganese content in infant foods and its bioavailability. In experimental animals, manganese deficiency has been shown to have severe effects on prenatal and postnatal development.¹ No cases of documented manganese deficiency have yet been reported in human infants, although concern about the risk for devel-

oping manganese deficiency has been discussed, especially for premature and low-birth-weight infants.^{2,3} This absence of cases, however, may also be from the lack of diagnostic tests for manganese deficiency. In contrast to iron, zinc, and copper, manganese stores are not thought to be accrued prenatally^{4,5}; thus, the infant may be particularly susceptible to manganese deficiency. Full-term infants have been described to be in negative manganese balance,² and very-low-birth-weight infants were shown to have an impaired manganese status, as assessed by manganese concentration in the hair.³ Some convulsive disorders have been proposed to be related to manganese deficiency.^{6,8} The low manganese level in blood observed in some young children has been postulated to be caused by an insufficient supply of manganese in utero or after birth.⁶

The toxic side effects of manganese may also be a problem early in life, since the manganese concentration of some infant formulas is high, in some cases exceeding the concentration in human milk by a factor of 200.^{9,10} This high concentration of manganese may be potentially deleterious to infants, since manganese homeostasis is mainly regulated through excretion via bile,¹¹ and biliary excretion is not established early in life.¹² In the adult human, it is well known that manganese toxicosis can have severe effects, particularly with regard to the central nervous system. Thus, a high supply of manganese during the neonatal period may be as detrimental to the infant as a deficiency.

Information on the bioavailability of manganese from infant diets is needed to establish a range for "safe and adequate daily dietary intake" for infants. Data from animal studies have shown that manganese absorption can be influenced by the level of iron¹³ and calcium¹⁴

as well as by other dietary factors, such as phytic acid intake.¹⁵ The content of these dietary components varies in milks and formulas, and it has been reported that some of these factors can affect trace element absorption, eg, zinc absorption from infant diets.¹⁶ We have recently developed a sensitive method to study manganese absorption in humans.¹⁷ The method involves feeding an extrinsically labeled test meal to an adult human and subsequently monitoring the whole-body retention of the administered radioisotope in a very sensitive whole-body counter. The aim of this study was to compare manganese absorption from human milk with cow's milk and infant formulas (based on cow's milk or soy), as well as to study the effect of iron fortification of formulas.

SUBJECTS AND METHODS

Subjects

Thirty-nine subjects, 12 men and 27 women, volunteered for the study. They were all healthy, none of the women were pregnant, and none of them had a history of gastrointestinal dysfunction. The mean age was 28 years (range, 21 to 45 years). None of the subjects was consuming vitamin or mineral supplements or any other medication during the study. Subjects were given written and oral information about the aims and procedures of the study, and informed consent was obtained from all participating subjects. The project was approved by the Ethical Committee and by the Isotope Committee of Sahlgrenska Hospital, University of Gothenburg, Göteborg, Sweden, and by the Human Subjects Committee at the University of California, Davis.

Diets

The following milks and formulas were used: (1) pooled and pasteurized human milk obtained from the milk bank at the Östra Hospital, Göteborg; (2) pasteurized and homogenized cow's milk (with 3% fat, purchased from a local vendor); (3) powdered,

whey-preponderant (60/40) cow's milk formula (Baby Semp 1, Semper AB, Stockholm, Sweden); (4) whey-preponderant (60/40) cow's milk formula (Enfamil, Mead Johnson, Evansville, Ind), either iron fortified (12 mg/L of iron, diet a) or the same formula without iron fortification (2 mg/L of iron, diet b); and (5) soy formula (Prosoabee, Mead Johnson). Milks and formulas were pooled and kept frozen in 450-g serving portions until used. Fifty-five grams of the powder (diet 3) was dissolved in deionized water (395 g); all other formulas were in liquid form. Milks and formulas were extrinsically labeled with 0.1 to 0.2 millibecquerel of manganese 54 or 0.3 mBq of manganese 52 before being served.

Paired observations were used to compare the manganese absorption from human milk with cow's milk (subjects 1 through 8) and to evaluate the influence of iron fortification (diet 4, subjects 23 through 30) as well as to compare the manganese absorption from the soy formula with whey-preponderant cow's milk formula with a high iron content (diet 4a, subjects 31 through 39). The whey-preponderant cow's milk formula in diet 3 was given as one single administration to 14 subjects (subjects 9 through 22).

Radioisotopes

The ^{54}Mn was purchased commercially for use in this study. The ^{52}Mn was produced for this study in the cyclotron at the Department of Physics, University of Oslo, Norway.¹⁸ Individual portions of the radioisotope stock solutions were diluted in deionized distilled water to a volume of 2 mL in standardized plastic capsules. The portions were measured in an activity calibrator and then added to the milk or formula before it was served. The empty vials were measured separately in the whole-body counter after the subjects had consumed the fluid.

Experimental Design

The subjects arrived in the morning after 12 hours of fasting. Measurements of height and weight were registered, and each subject's background radioactivity was measured in the whole-body counter. Blood samples were drawn in the fasting state for determination of the whole-blood manganese and iron status. The extrinsically labeled test meal was served, and a 100% value of administered activity was obtained by measurement in the whole-body counter immediately after intake. No other food or fluid was allowed during the next 3 hours. The subjects maintained their normal food intake during the study. The two test meals were served on 2 consecutive days with ^{54}Mn and ^{52}Mn as a label, or with a time lapse of approximately 2 months when ^{54}Mn was administered twice. Whole-body retention measurements were

performed two to three times weekly during approximately 30 days after initiating the study.

The whole-body counter laboratory at the Radiation Physics Department at the University of Gothenburg is equipped with a double-chamber iron room with 150-mm-thick walls containing two different detector systems for whole-body measurements.¹⁹ Detector system 1, which was used in this study, consists of two 130 × 100-mm sodium iodide (TI) detectors (Bicron Corp, Newbury, Ohio) mounted on opposite sides of a patient couch and attached to a motor-driven *x-y* scanning system. The most important property of these detectors is their spectral resolution that enables studies of more than one isotope simultaneously in the body; in this case, we were able to measure ^{52}Mn in the presence of ^{54}Mn when the two radioisotopes were administered on consecutive days.¹⁸ Manganese absorption was calculated by extrapolation to day 0 from whole-body retention measurements during days 10 through 30.¹⁷ The resulting radiation exposure of the subjects was evaluated using the model of the International Commission on Radiological Protection,^{20,21} which gives the exposure of the whole body (effective dose equivalent) after ingestion of a certain activity. In this study, the radiation exposure was 0.07 to 0.6 mSv to each subject.

Analysis

Indexes of iron status were determined by routine laboratory methods. Whole-blood manganese was analyzed by electrothermal atomic absorption (using a Perkin Elmer Zeeman/3030 instrument equipped with graphite furnace HGA 600; Perkin Elmer, Überlingen, West Germany). Magnesium nitrate was used as a matrix modifier.²² Aliquots of milks and formulas were freeze-dried and homogenized before analysis. The manganese content in the diets was analyzed by electrothermal atomic absorption. Before analysis, the food items were wet ashed in an autoclave (Perkin Elmer Autoclave-3), 1 g of freeze-dried sample was added to 6 mL of 7 mol/L of nitric acid and heated to 160°C during 1 hour. After wet ashing, the samples were made up to 25 mL with deionized distilled water. The content of minerals (iron, calcium, and magnesium) was determined by atomic absorption spectrophotometry (Perkin Elmer Model 360). An analysis of iron content was done after dry ashing (450°C), while concentrations of calcium and magnesium were determined after wet ashing (290°C to 300°C) in sulfuric acid and hydrogen peroxide and after the addition of lanthanum oxide. The same digest was used to determine phosphorus concentrations by the Fiske-Subbarow method.²³ Nitrogen analysis was performed by a micro-Kjeldahl tech-

nique (Technicon Autoanalyzer, Ardsley, NY). Phytic acid content in the soy formula was determined as described by Davies and Reid.²⁴

Statistics

For statistical evaluation of absorption data, Student's *t* test for paired samples was used for comparison of diets 1 and 2, 4a and 4b, and 5 and 4a. Analysis of variance and Duncan's New Multiple-Range Test was used for tests of statistical significance when other comparisons were made (Mulreg 800; Idatron, Linköping, Sweden).

RESULTS

The mean whole-blood manganese concentration of the participating subjects was 0.22 $\mu\text{mol/L}$ (range, 0.13 to 0.37 $\mu\text{mol/L}$). Analyzed laboratory values were as follows: hemoglobin, 122 to 150 g/L for women and 139 to 166 g/L for men; serum iron, 10 to 30 $\mu\text{mol/L}$ for women and 13 to 40 $\mu\text{mol/L}$ for men; and total iron-binding capacity, 48 to 76 $\mu\text{mol/L}$ for both women and men. All values for whole-blood manganese and iron status indexes were within the normal range for our laboratory. Concentrations of nitrogen, iron, calcium, phosphorus, and magnesium in the milks and formulas studied are given in Table 1. The concentration of phytic acid in the soy formula was 460 $\mu\text{mol/L}$. The content of manganese and iron in the diets and manganese absorption from the diets are shown in Table 2.

Fractional manganese absorption from human milk was significantly higher than the absorption of manganese from cow's milk, whey-preponderant cow's milk formula (with or without iron fortification, diets 4a and 4b), and soy formula. No significant difference was observed, however, between human milk and the whey-preponderant cow's milk formula with 7 mg/L of iron, diet 3. The manganese absorption from this formula (diet 3) was significantly different from that of the other test meals. No significant difference in manganese absorption was observed after the administration of the two formulas differing only in iron content (diets 4a and 4b) to the same group of subjects. The administration of soy formula was found to result in a significantly lower fractional manganese absorption compared with the iron-fortified cow's milk formula (diet 4a) when results from the paired

Diet	Nitrogen, g/L	Iron, mg/L	Calcium, mg/L	Phosphorus, mg/L	Magnesium, mg/L
1. Human milk	2.4	0.7	294	200	32
2. Cow's milk	5.1	0.2	1033	737	65
3. Cow's milk formula (Baby Semp 1)	2.2	7	392	303	54
4a. Cow's milk formula (Enfamil), iron fortified	2.4	12	427	303	76
4b. Cow's milk formula (Enfamil), non-iron fortified	2.3	2	410	303	76
5. Soy formula (Prosobee)	3.1	12	454	475	70

Diet	Subjects	Manganese, μ g	Iron, mg	Manganese Absorption*	
				%	μ g
1. Human milk	1-8	7.2	0.27	8.2 \pm 2.9 ^a	0.59 \pm 0.21 ^a
2. Cow's milk	1-8	44	0.13	2.4 \pm 1.7 ^b	1.06 \pm 0.75 ^{a,b}
3. Cow's milk formula (Baby Semp 1)	9-22	23	3.0	5.9 \pm 4.8 ^a	1.36 \pm 1.10 ^{a,b}
4a. Cow's milk formula (Enfamil), iron fortified	23-30 and 31-39	59	5.6	1.7 \pm 1.0 ^b	1.00 \pm 0.59 ^{a,b}
4b. Cow's milk formula (Enfamil), non-iron fortified	23-30	59	1.0	3.1 \pm 2.8 ^b	1.83 \pm 1.65 ^b
5. Soy formula (Prosobee)	31-39	132	7.2	0.7 \pm 0.2 ^b	0.92 \pm 0.26 ^{a,b}

*Values are given as means \pm SDs. Values with different superscript letters within each column were significantly different ($P < .05$) (using analysis of variance and Duncan's New Multiple-Range Test).

observations were evaluated ($P < .02$). Due to the differences in manganese content, the total amount of absorbed manganese was significantly higher from the whey-preponderant cow's milk formula without iron fortification (diet 4b) as compared with human milk, while no significant differences were observed when the total amount of absorbed manganese was calculated for the other milks and formulas studied.

COMMENT

There is a pronounced effect of age on the percentage of manganese retained from a meal in young rats.^{26,28} A higher capacity for manganese absorption and retention in young animals compared with older animals may be a consequence of the scarcity of this essential

trace metal in the diet.²⁷ Raghib et al²⁶ proposed that the observed effect of age on manganese absorption might be caused by the degree of passive transport and that the lower manganese absorption by older rats might be caused by intestinal maturation rather than by the nutritional need for manganese. In our study, manganese absorption from infant diets was studied in adults. Whether the differences found between diets would be more pronounced when studied in infants is not known, although this seems to be the case for zinc, when studied in monkeys.²⁸

Manganese absorption was estimated in adult humans by using a radioisotope technique in this study. Highly reproducible figures for manganese absorption within the same individual have

been found using this technique.¹⁷ Inter-individual variation in manganese absorption was shown, however, to be substantial, indicating that the best way to identify factors influencing manganese absorption is by paired observations, with subjects acting as their own controls. Because of practical reasons, diet 3 was given as one single test meal, while the other diets were served at two occasions, eg, human vs cow's milk, to the same subject to obtain paired observations. The administration of ⁵⁵Mn and ⁵⁴Mn was done on consecutive days when possible. However, ⁵⁵Mn is not available commercially but was produced for this study. Because of the short half-life (5.7 days) and the tedious procedure of production, the isotope was not available at all times during the study. Consequently, ⁵⁴Mn was used as an extrinsic label for both diets.

The validity of the extrinsic labeling of the meals has been reported earlier.^{18,29} Equal distribution of native manganese and the added radioisotope within individual fractions of human milk, cow's milk, and infant formulas were demonstrated and can be regarded as an indirect validation of the extrinsic labeling technique for these particular diets.²⁹ The method has also been directly validated using simultaneous measurements of ⁵⁴Mn and ⁵²Mn added intrinsically and extrinsically to chicken liver.¹⁸

Human milk and formulas have previously been evaluated with regard to manganese absorption in animal studies and in a few studies of human infants. A high bioavailability of manganese during the suckling period in rats has been reported for infant diets.²⁶ The mean relative retention of manganese, measured by a chemical balance technique in infants, was 43% for human milk and 20% when cow's milk formula was fed.³⁰ Our results demonstrated high bioavailability of manganese from human milk. This is consistent with earlier studies in which high bioavailability of trace minerals in human milk has been reported for zinc,¹⁵ iron,³¹ and copper.³² The reasons for the difference in manganese absorption from human milk as compared with cow's milk are not yet known. It is not likely to be caused by the difference in manganese concentration, however, as manganese absorption from a vitamin and mineral supple-

ment containing 2.5 mg of manganese sulfate was found to be $9\% \pm 3\%$ when the supplement was taken in a fasting state by six healthy subjects.³³ A possible explanation of the differences in manganese absorption between human milk and cow's milk is that manganese in human milk, but not in cow's milk, is bound to lactoferrin.³⁹ Lactoferrin has been shown to bind to a specific receptor in the small intestine,³⁴ and it has recently been shown that lactoferrin efficiently delivers not only iron but also manganese.³⁵ Lactoferrin may therefore provide a mechanism for manganese absorption from human milk as well as for iron absorption. Furthermore, cow's milk contains a considerably higher amount of calcium as compared with human milk, which may have influenced the manganese absorption. The adverse effect of calcium on manganese absorption has been reported.¹⁴

The interaction between iron and manganese has been demonstrated in several investigations.^{13,36-39} In this study, we found that the iron fortification of the cow's milk formula (diet 4a) led to a lower mean fractional manganese absorption as compared with the identical formula without iron supplementation (diet 4b), although the difference was not statistically significant. Administration of the cow's milk formula with 7 mg/L of iron (diet 3) was shown to result in a significantly higher manganese absorption as compared with the cow's milk formula containing 12 mg/L of iron (diet 4a) as well as compared with the non-iron-fortified formula (diet 4b). The differences observed in manganese absorption from whey-preponderant cow's milk formulas can thus not be explained by the different iron content. A possible factor influencing manganese absorption is, however, the protein composition. The cow's milk formulas (diets 3, 4a, and 4b) were all whey-preponderant (60/40). However, there are significant differences in the nitrogen and nonprotein nitrogen composition of formulas from different manufacturers. These differences are from the use of heat treatment during processing and depend on the source of whey used for the whey adjustment.⁴⁰

The low fractional manganese absorption from soy formula demonstrated in this study is consistent with

results from animal studies.²⁵ The low bioavailability of zinc in soy formula has been demonstrated in adult humans with the use of a radioisotope technique.¹⁶ Soy formula contains a considerable amount of phytic acid and proteins with different characteristics as compared with the other infant diets studied,⁴⁰ which may, at least in part, explain the low fractional manganese absorption from soy formula.

Since most formulas contain a considerably higher manganese content than what is found in human milk, manganese deficiency may be less of a concern than the toxic side effects of manganese when formulas are fed. When the total amount of absorbed manganese was calculated, the whey-preponderant cow's milk formula with low iron content (diet 4b) provided three times as much manganese as human milk ($P < .05$). This high amount of absorbed manganese might be detrimental to the child since excretion of manganese is low early in life.^{11,12} Thus, the body burden of manganese might be significantly increased in formula-fed infants as compared with breast-fed infants.

The optimum amount of manganese as well as the ratios between the content of different trace elements in infant diets need to be determined. Studies of manganese absorption in infants as well as further studies to identify factors affecting manganese absorption are needed before "a safe and adequate" range for manganese intake can be established.

This study was supported by grant 85-CRCR-1-1582 from the US Department of Agriculture, Washington, DC, and by Semper AB.

The authors wish to thank Einar Hagebø, PhD, from the Department of Chemistry, University of Oslo (Norway), for the ⁵²Mn used in this study.

Book Review

Otitis Media in Infants and Children, by C. D. Bluestone and J. O. Klein, 288 pp, with illus, \$39.95, Philadelphia, Pa, WB Saunders Co, 1987.

This useful book has 10 chapters, the first 6 dealing with basic sciences and the last 4 addressing clinical disease and management. The authors are well qualified, having written more about this subject than any of their contemporaries. All their publications have reflected well-constructed, controlled studies.

Caveats for initial evaluation of children with otitis media are presented, coupled with a brief differential diagnosis of other conditions that cause conductive hearing loss: traumatic or erosive ossicular chain disruption and atelectasis of the tympanic membrane associated with ossicular discontinuity or an acquired cholesteatoma. There is an excellent section on normal eustachian tube function and dysfunction due to maldevelopment of the cranial base or intrinsic mechanical obstruction by polyps or cholesteatoma.

Knowledge of the epidemiology of middle-ear disease in children is a recent development. Longitudinal studies of American Indian and Alaskan children are presented. Otitis media unrecognized by parents, because it was asymptomatic, can be diagnosed using immittance studies and audiograms and by pneumatic otoscopy. Sex, race, socioeconomic factors, congregating children in child-care facilities, season of the year, genetic factors, breast-feed-

ing, and effects of altered host defenses or underlying disease singly or as a result of multiple factors may contribute to the size and complexity of the problem. Relevant microbiologic and immunologic studies are reviewed in a detailed, well-classified format. The signs and symptoms are described, along with a chart showing tympanogram types and variants related to clinical findings, which will be useful to the general physician and pediatrician. The chapter on diagnosis is quite complete, with discussions of otoscopy, tympanograms, acoustic reflexometry, and auditory brain responses. Various techniques of obtaining hearing thresholds on children are well illustrated. Sections on high-risk populations, the deaf, and methods of collecting specimens are included. Clinical eustachian tube tests are also described clearly.

Options for managing various stages of otitis media represent most of the philosophies in this country. An algorithm is provided. Another table provides a daily dosage schedule for useful antimicrobial agents in otitis media and likely would be a valuable quick reference, complete with dosages per unit weight of the child.

Risk Factors for Infant Botulism in the United States

John S. Spika, MD; Nathan Shaffer, MD; Nancy Hargrett-Bean, PhD;
Sheila Collin; Kristine L. MacDonald, MD; Paul A. Blake, MD, MPH

• To define risk factors for infant botulism, we performed a 2-year prospective case-control study of 68 laboratory-confirmed cases in infants living in the United States, outside of California. For each case patient, two control subjects were matched by date and hospital of birth or county birth records. By univariate analysis, breast-feeding (odds ratio=2.9) and consumption of honey (odds ratio=9.8) were associated with disease, but only 11 case patients (16%) had eaten honey. Decreased frequency of bowel movement (less than one per day for at least 2 months) was also associated with disease in infants 2 months of age and older (odds ratio=5.2). Risk factors changed with the age of the patient at disease onset when analyzed by multivariate logistic regression methods. For infants less than 2 months old, living in a rural area or on a farm was the only significant risk factor (odds ratio=6.4). For infants 2 months of age and older, breast-feeding (odds ratio=3.8), less than one bowel movement per day for at least 2 months (odds ratio=2.9), and ingestion of corn syrup (odds ratio=5.2) were associated with disease. The severity of the disease was similar for breast- and bottle-fed infants. Clearly defined food exposures account for a minority of infant botulism cases. Preexisting host factors, such as intestinal flora and frequency of bowel movements, may be the most important risk factors for development of disease.

(AJDC. 1989;143:828-832)

Over 600 cases of infant botulism have been reported in the United States¹ since the first description of this disease in 1976,² making it the most common form of botulism identified in this country. Epidemiologic studies have identified consumption of honey and breast-feeding as risk factors for disease.^{3,4} Spores of *Clostridium botulinum* of the same toxin type causing disease have been isolated from honey fed to infants before onset of illness.^{3,6} Although 27% to 29% of patients described in two large

early studies received honey,^{3,6} this exposure is now identified for about 15% of cases reported to the Centers for Disease Control (CDC), Atlanta, Ga, through a nationwide surveillance system for infant botulism (unpublished data, 1935). No other potential food source in infants for *C botulinum* spores has been epidemiologically implicated. However, spores have occasionally been isolated from corn syrup.⁷ Epidemiologic and microbiologic evidence implicating commercial food products would support interventions aimed at better consumer education.

The role of breast-feeding remains controversial. From 66% to 100% of patients with infant botulism described in previous studies have been breast-fed.^{4,6,9} These infants were predominantly white, and their mothers tended to be older and have more years of education than the general population,⁶ factors associated with a greater tendency to breast-feed.¹⁰ These studies have not determined if breast-feeding contributes to infant botulism or if breast-feeding is simply a confounding factor that, like some as yet undetermined causal factor, is associated with socioeconomic status.

Breast-fed infants may have better access to physicians more likely to make the diagnosis. It has been proposed that breast-fed infants with infant botulism are identified because they have milder disease with later onset, while non-breast-fed infants present earlier with a clinical picture identical to sudden infant death syndrome.⁸ We performed a case-control study to better define the role of breast-feeding as a risk factor for disease and to identify other foods and host and environmental factors that may contribute to acquisition of infant botulism.

METHODS

All laboratory-confirmed cases of infant botulism outside of California reported to CDC with onset of disease from April 1, 1985, to March 31, 1987, were eligible for inclusion in the study. Most state laboratories do not test for *C botulinum* or its toxin and send stool specimens from suspected cases of bot-

ulism to CDC for analysis. State laboratories that process specimens from suspected cases of botulism report all laboratory-confirmed illness to CDC.

Following notification, we interviewed by telephone the patient's physician regarding the illness and hospitalization and obtained permission to interview the case patient's family. Each case patient was matched with two control subjects by identifying the next four infants who were born after the case patient at the hospital of birth. Information was obtained on the first two identified infants who were alive and living at home and whose physician and parents agreed to participate. For six case patients, the names of potential matching control subjects were obtained from records of the case patient's county of current residence for births on the same day. Two were born at home, two had moved to another state at least 1 month before onset of illness, and the hospital of birth refused to identify control subjects for two of the infants.

Case patients' and control subjects' families were interviewed by telephone using a standardized questionnaire. Case patients' families were asked about signs associated with infant botulism and the date each sign was first noticed. Since the onset of infant botulism can be insidious, onset of illness was defined as the date the patient was first seen by a medical person for illness subsequently identified as infant botulism.

Information was obtained from the families of case patients and control subjects about sources of medical care for the infant, previous medical problems, immunizations, the mother's pregnancy, the infant's usual bowel movement (BM) pattern by month of life (at least one BM per day; less than one BM per day, but at least one BM per 3 days; or less than one BM per 3 days), occupation, and educational levels of both parents, and usual activities around the home. Information about type and quantity of all food exposures, supplemental vitamins, pacifier use, location of residence (defined by the parent as city, suburban, rural, or on a farm), and environmental events was obtained for the 1-month period before onset of illness.

Parents were asked to quantify breast-milk consumption as a percentage of all milk or formula fed during the month. Specific questions were asked about events that occurred within 300 ft of the home, including construction (new home or other building), excavation (sewers or new foundations), new road construction, plowing of fields, and environmental changes (remodeling of home or

Accepted for publication February 13, 1989.

major landscaping). If an infant spent at least 20 hours per week at a location other than his home during the 1-month period, similar information was obtained about that location from a source identified by the parent.

A socioeconomic status score was determined for the family (parent's highest score) using the index of Stevens and Featherman.¹¹ Exposures in case patients and control subjects were compared using the Pike and Morrow extension of the Mantel-Haenszel χ^2 test.¹² Where indicated, the χ^2 test for linear trend and multivariate logistic regression analysis¹³ were used.

RESULTS

Sixty-eight (99%) of 69 laboratory-confirmed cases of infant botulism (33 type A and 35 type B) that were reported to CDC with onset of disease April 1, 1985, to March 31, 1987, were included in the study. One patient (type A) was excluded because control subjects matched from county records could not be contacted. The median age of the 68 case patients at "onset of illness" was 2.0 months (range, 0.2 to 11.7 months). Fifty-three percent were female. Sixty-six case patients (97%) were hospitalized for a median of 27 days (range, 1 to 152 days) and 28 (42%) required ventilator support for a median of 19 days (range, 4 to 80 days).

The most common first symptoms observed by parents were poor feeding (52%), less than one BM per 3 days (47%), and altered cry (25%). Forty-seven (69%) had less than one BM per 3 days for a median of 4 days (range, 0 to 117 days) when first seen with symptoms of botulism by a medical person. One patient had a respiratory arrest after botulism was diagnosed, suffered severe brain damage, and died 6 months later.

Two control families were interviewed for each of 67 case patients. Only one control family was interviewed for 1 of the case patients. Information on case patients and control subjects for some of the variables examined is presented in Table 1. Among food items, significant differences between groups were detected only for exposure to breast milk and honey during the month before onset of illness in the case patient. Corn syrup was used by 29% of the case patients and 19% of the control subjects. Overall, control subjects had foods other than breast milk introduced earlier

*Based on the Stevens and Featherman¹¹ index.

†This category includes a total of 35 case patients and 70 control subjects at least 2 months old.

‡One case patient moved from city to suburb during the month before illness onset and is included in both locations.

than case patients. However, no difference was found when infants receiving formula at birth were excluded from the analysis.

Decreased frequency of BM was associated with illness. Thirty-seven (64%) of 58 case patients at least 1 month old had a usual monthly pattern before onset of illness of one BM per day compared with 17 (15%) of 115 control infants ($P<.001$; odds ratio=13.8; 95% confidence interval=4.9, 39.1). Forty-seven percent of the case patients and 14% of the control subjects had less than one BM per day, but had at least one BM every 3 days during this period ($P<.001$; odds ratio=6.7; 95% confidence interval=2.7, 16.4). Since "constipation" is a prominent symptom of infant botulism reported in the litera-

ture and its presence for more than a few days could affect the reported usual monthly pattern, we determined the number of infants with less than one BM per day for 2 months before onset of illness (Table 1). The association with less than one BM per day remained significant.

Case patients were more likely than control subjects to have lived in a rural area or on a farm. Differences between case patients and control subjects were not detected for frequency of dusting or vacuuming at home, type of home heating and cooling systems, number and location of house plants, or frequency of gardening by family members. Eighteen percent of the case patients and 15% of the control subjects spent at least 20 hours per week away from home

during the month before the case patient's illness. No significant differences were detected when these exposures were analyzed.

To determine whether the increased use of corn syrup by case patients was due to their greater likelihood of receiving corn syrup for treatment of decreased frequency of BM, corn syrup use was stratified by frequency of BM during the 2-month period before onset of illness in the case patient. Only infants 2 months of age or older were included in the analysis. Among infants with at least one BM per day for the 2-month period, 44% of 9 case patients and 13% of 47 control subjects had ingested corn syrup. Among those with less than one BM per day, 29% of 17 case patients and 18% of 11 control subjects had ingested corn syrup. Matched analysis could not be done because of an insufficient number of case patient and control subject pairs and triplets.

Analysis of infants by multivariate linear logistic regression analysis using risk factors identified as significant ($P \leq .05$) or of borderline significance ($P < .1$) in univariate analyses is shown in Table 2. No significant interactions were detected among the variables included in these analyses. Breast-feeding and honey ingestion during the month before onset of illness were significant risk factors when rural or farm residence and consumption of corn syrup were controlled.

Separate logistic models were developed for infants less than 2 months old ($n = 98$) and 2 months of age and older ($n = 105$) so that BM pattern (less than one BM per day) during the 2 months before onset of illness could be analyzed. Honey was not included in these models because case patients and control subjects exposed to honey were divided between the less than 2-month-old group and the 2-month and older group; the number of infants in each group was too small. Only rural or farm residence was associated with disease in the younger than 2-month-old group; this variable was not a risk factor for those 2 months of age or older. Breast-feeding, decreased BM frequency, and corn syrup were risk factors for the 2-month and older group (Table 2), although decreased BM frequency had only borderline significance ($P = .072$).

Table 2.—Multivariate Logistic Regression Analysis of Selected Risk Factors

Model	No. of Case Patients	No. of Control Subjects	Odds Ratio	95% Confidence Interval	P Value
Model 1 (all infants)					
Honey	16	2	8.3	1.7, 39.3	.007
Corn syrup	29	19	2.0	0.9, 4.6	.097
Breast-fed	74	47	3.3	1.6, 6.6	.001

Rural/farm	11	13	1.1	0.3, 4.6	.936
Decreased bowel movements†	66	19	2.9	0.9, 9.5	.072

*The infants lived in a rural area or on a farm during the month before onset of illness.

†The infants had less than one bowel movement per day for at least 2 months before onset of illness.

Fig 1.—Breast-feeding status of case patients and control subjects.

To evaluate whether confounding was present in the multivariate logistic model for infants 2 months of age and older, we included corn syrup ingestion, breast-feeding, and rural/farm residence individually with decreased BM frequency in separate logistic models. Decreased BM frequency was a significant risk factor in each model with odds ratios that varied between 3.8 and 5.3. The odds ratio for decreased BM fre-

quency was always greater than the odds ratio for the other variable. This suggested to us that the change in level of significance for decreased BM frequency in the model with all four variables was due to inadequate power with a small number of case patients and control subjects.

The percentage of case patients and control subjects breast-fed by age at disease onset is shown in Fig 1. There

Fig 2.—Percentage of infants requiring ventilator support, by age and breast-feeding status.

was a trend toward increased breast-feeding with increasing age among case patients ($P = .014$, χ^2 for linear trend). However, the difference between case patients and control subjects by matched analysis was not significant until 3 months of age ($P = .05$; odds ratio = 4.9; 95% confidence interval = 1.0, 24). To examine the effect of breast-feeding on severity of disease, we looked at the percentage of infants requiring ventilator assistance by age and breast-feeding status (Fig 2). There was a tendency toward greater need for ventilator assistance with younger age, but this was not significant ($P = .122$, χ^2 for linear trend). No marked difference was seen between breast-fed and non-breast-fed infants.

COMMENT

The results of this study demonstrate that decreased frequency of BM 1 and 2 months before onset of illness is associated with acquiring infant botulism. Decreased BM frequency has not been recognized previously as a risk factor, although infants may have several weeks of constipation before the appearance of other symptoms.¹⁴ It has been difficult to determine whether constipation is a risk factor for, or a result of, the disease because the incubation period for infant botulism is unknown. However, epidemiologic and clinical information suggest that the incubation period is less than 1 month. In this study, 10 infants (15%) were younger than 30 days of age when first seen by a

medical person for their illness, and 1 infant was only 6 days old. The 47 infants who had at least one BM every 3 days before they were seen by a medical person had had this BM pattern for a median of only 4 days before the visit. It is unlikely that the 23 case patients (66%) at least 2 months old with decreased BM frequency all had incubation periods of 2 months or longer.

Decreased BM frequency may be a sign of decreased intestinal motility, which could give ingested *C botulinum* spores increased opportunity for germination and toxin production. In adults, decreased motility can be reflected in decreased stool volume,¹⁵ and may contribute to the bacterial overgrowth syndrome.¹⁶ Decreased motility may also permit retrograde movement of *C botulinum* or its toxin from the colon into the ileum. In adult germ-free mice, removal of the cecum prevents colonization by *C botulinum* and development of botulism after challenge with spores.¹⁷ However, it is thought that most toxin is absorbed from the small intestine, because morbidity in mice following challenge with spores is better correlated with the amount of toxin present in the small intestine than with the amount in the colon,¹⁸ and toxin injected into the colon of rhesus monkeys is poorly absorbed.¹⁹

Consumption of honey continues to be associated with infant botulism. Unlike the earlier report identifying an association only between honey ingestion and disease with *C botulinum* type B,³ both type A (five cases) and type B (six cases)

disease occurred in case patients exposed to honey in this study.

Microbiological surveys of honey have found that 4% to 25% of samples contain *C botulinum* spores.²⁰⁻²² Honey should not be fed to infants younger than 1 year old, especially those younger than 6 months old.²³ One of the case patients in this study was older than 11.5 months at onset of illness. The infant was receiving breast milk, had had less than one BM per day for 6 months, and was fed a commercial honey-yogurt product during the month before developing infant botulism. Even 1-year-old infants may remain susceptible to intestinal colonization and toxin production by *C botulinum*.

An important finding of this study was that illness in infants younger than 2 months old is epidemiologically different from that in older infants. Sources of *C botulinum* spores for the youngest infants are a mystery because these infants have few environmental exposures and are rarely given foods other than breast milk and formula. Yet, almost half the reported cases of infant botulism in the United States occur in this age group. Breast-feeding was not a risk factor for this group, but living in a rural area or on a farm was associated with disease and reported by 40% of the families of case patients (Table 2). While it remains unclear how these infants came into contact with *C botulinum* or its spores, environmental contamination by this organism may be greater in rural settings.

Breast-feeding was associated with disease in infants at least 2 months old. Illness did not appear to be less severe for breast-fed infants than for non-breast-fed infants. The severity of illness tended to be greater in younger infants, whether they were breast-fed or not. Since maternal age and education and family occupational status were similar between case patients and control subjects, it is unlikely that the increased risk associated with breast-feeding was due to socioeconomic factors. The increased risk with increasing age for infant botulism among breast-fed infants suggests that factors associated with breast milk may be important. However, infant botulism is a rare disease⁶ and breast-feeding should be encouraged because its benefits far

outweigh the increased risk for infant botulism.

A unifying hypothesis that would explain the differences between infants younger than 2 months old and those 2 months of age and older is that breast-feeding may prolong susceptibility to colonization by *C botulinum*. All infants younger than 2 months old may be highly susceptible to colonization by *C botulinum* because of a poorly developed anaerobic fecal flora. Anaerobic bowel flora protect adult mice from colonization by *C botulinum*; pretreatment of the mice with metronidazole makes them receptive to colonization and the development of botulism after orogastric inoculation of *C botulinum* spores.¹⁸ Significant differences in the frequency of isolation of *Clostridium* species have been observed between breast- and bottle-fed infants.^{24,29} Extracellular factors of *Clostridium sporogenes* inhibit growth and lyse *C botulinum*.³⁰ The presence of other clostridial species may prevent intestinal colonization by *C botulinum*.

Corn syrup, like honey, is used as a sweetener for infants and to treat constipation. In a nationwide survey, spores of *C botulinum* were isolated from 0.5% of 961 bottles of corn syrup.⁷ Follow-up testing of corn syrup has continued to yield "low" levels of *C botulinum* spores.³¹ Corn syrup use was not identified as a risk factor in an earlier epidemiologic study in California.³

Odds ratios for corn syrup use in our study were elevated for all infants when analyzed in univariate and logistic regression analyses. When infants at least 2 months old were analyzed separately, the association between corn syrup use and development of infant botulism was significant. Corn syrup use was greatest for case patients who had at least one BM per day. This suggests that the increased risk for infant botulism among infants receiving corn syrup is not confounded by the use of corn syrup to treat infants with decreased BM frequency. The data are inconclusive, and additional studies are necessary to determine if the use of corn syrup is a risk factor for infant botulism.

Prevention of some cases of infant botulism may be possible through more extensive educational campaigns discouraging the use of honey. Since 11

(79%) of 14 honey products consumed by case patients and control subjects in this study were from commercial sources, use of warning labels on epidemiologically and microbiologically implicated food items may help prevent feeding of these items to infants.

The majority of cases, however, will not be prevented by these measures. Awareness of this disease and its risk factors by physicians will continue to be important to ensure early supportive care and to prevent death. The diagnosis of infant botulism was considered to be early in most patients enrolled in this study; two had mild symptoms and were not hospitalized. Many of the responsible physicians had previously cared for infants with this rare disease. However, many cases may escape diagnosis.

All afebrile infants who develop decreased ability to feed and in whom no other infectious cause is identified should have stool specimens submitted for culture of *C botulinum* and detection of toxin, particularly if there has been a change toward a less frequent BM pattern.

The authors thank Charles L. Hatheway, PhD, for his laboratory support and Stephen S. Arnon, MD, MPH, for his advice on design of our survey instrument.

We also thank the many state epidemiologists and their coworkers who reported cases to us, the hospital personnel who assisted in this study, and the physicians and parents who took the time to participate in interviews.

Neurofibromatosis Type 1 (Recklinghausen's Disease)

Neurologic and Cognitive Assessment With Sibling Controls

Roswell Eldridge, MD; Martha B. Denckla, MD; Ellen Bien, PhD; Susan Myers, MD; Muriel I. Kaiser-Kupfer, MD; Anita Pikus, MS; Sandra L. Schlesinger, MS; Dilys M. Parry, PhD; James M. Dambrosia, PhD; Michael A. Zasloff, MD, PhD; John J. Mulvihill, MD

• Neurologic and cognitive function in neurofibromatosis type 1 (NF1) were assessed in a controlled pilot study of 13 pairs of siblings aged 6 to 27 years. One subject in each pair was affected with NF1, and the other, the control subject, was unaffected. Subjects with evidence of focal central nervous system disease were excluded. The 13 subjects with NF1 had no excess of mental retardation, attention-deficit disorder, or specific learning disorders (using Wilcoxon's Signed Rank Test and McNemar's Test for Symmetry). These subjects, however, had significantly higher scores for subtle neurologic abnormalities (21 vs 6) and significantly lower full-scale IQ scores (94 vs 105) than their unaffected siblings. The IQ scores of the affected subjects were not clustered at the lower end of the scale but showed a slight downward shift in distribution compared with those of their siblings. In addition, a visual-spatial orientation deficit was present in eight of nine affected subjects so evaluated. The findings suggest that subjects with NF1 have a widespread alteration of the brain during development that manifests as one or more specific types of neuropsychologic deficits.

(AJDC. 1989;143:833-837)

Neurofibromatosis type 1 (NF1), also known as Recklinghausen's disease, is one of the most common single-gene disorders of the human nervous system; it affects approximately 100 000 people in the United States.¹ The disease is characterized by café au lait spots, neurofibromas of the skin, and iris hamartomas (Lisch nodules).² The skeletal, central nervous, and endocrine systems may also be involved. Cognitive dysfunction and other developmental disabilities are said to occur in as many as 40% of patients,^{3,7} but there has been no rigorous, controlled neuropsychologic assessment of this issue.

This article describes a pilot study designed to assess subtle neurologic abnormalities, impaired cognitive function, and developmental disabilities in NF1, with the use of unaffected siblings as controls.

SUBJECTS AND METHODS Study Population

Subjects with NF1 and unaffected sibling controls for each were sought by mailing a letter to 350 local families known to the Interinstitute Medical Genetics Clinic at the Warren Grant Magnuson Clinical Center, National Institutes of Health, Bethesda, Md, and the Neurofibromatosis Clinic at Children's Hospital National Medical Center and the Metropolitan Washington Chapter of the National Neurofibromatosis Foundation, Washington, DC. With their informed consent, potential subjects and available first-degree relatives were screened by physical and neurologic examination, including ophthalmologic and audiologic evaluations. According to criteria modified from Winter et al,^{2,8} affected subjects had to have at least two of the following signs of NF1, which could not be explained by another disease process: (1) at least five café au lait spots 0.5 cm or greater in diameter if prepubertal and

at least six café au lait spots 1.5 cm or greater in diameter if older, (2) at least two cutaneous or subcutaneous lumps suggestive of neurofibromas, (3) biopsy-proved neurofibroma, (4) axillary or inguinal freckling, (5) Lisch nodules of the iris, (6) characteristic bone abnormality, such as pseudoarthrosis of the tibia or fibula, and (7) an affected parent or sibling, diagnosed by the aforementioned criteria.

Siblings were excluded as controls if they had any of the following: (1) one or more café au lait spots 0.5 cm or greater in diameter if prepubertal or 1.5 cm or greater in diameter if older, (2) one or more cutaneous or subcutaneous lumps, (3) axillary or inguinal freckling, (4) Lisch nodules of the iris, and (5) any bone abnormality characteristic of NF1. In a sibship in which there were two or more siblings who met the criteria for controls, we selected the sibling who was of the same sex as the subject and closest in age.

To avoid selection bias, affected subjects were excluded if the presence of a documented or suspected developmental disability, such as dyslexia, led to the diagnosis of NF1. To avoid confounding factors, affected subjects and sibling controls were excluded if there was evidence by medical history or cranial computed tomography (CT) of a neuropathologic process, such as epilepsy or brain tumor, or if the subject was taking medication on a long-term basis for any reason.

Assessment

Neurologic function was assessed by the Physical and Neurological Examination for Subtle Signs (PANESS),⁹ which is divided into the following five sections: (1) subtle neurodevelopmental abnormalities in gross and fine-motor function, (2) overflow phenomena, (3) sensory function, (4) handedness, and (5) tasks such as walking 10 paces heel to toe, rapid tongue wiggling, and hopping on one foot up to 30 times. These tasks were performed by all subjects in the same order and were evaluated and scored by the same observer. The PANESS was scored

Reprints not available.

from 0 (normal) to 5 (markedly abnormal). The neurologic assessment was completed in 20 to 30 minutes.

Neuropsychologic function was assessed by the Visual-Motor Integration Test,¹⁰ the Facial Recognition Test,¹¹ and the Iowa Judgment of Line Orientation Test.¹¹ Developmental disabilities involving cognitive function were evaluated by the tests and diagnostic criteria shown in Table 1. The IQ test selected for each subject was determined by the age range for which it was normalized. The Iowa Judgment of Line Orientation Test was not administered to subjects younger than 8 years of age, since normative data are not available for this age group. Each sibling of a pair was tested in the same room and at the same time on consecutive days. The tester had no knowledge of which sibling was affected, but no attempt was made to mask the features of NF1. The neuropsychologic and cognitive testing was completed in approximately 2½ hours.

Statistical Analysis

The Wilcoxon Signed Rank Test²² was used to compare the neurologic and cognitive function assessments of the affected subjects and sibling controls, and McNemar's Symmetry Test^{23,24} was used to compare their neuropsychologic function.

RESULTS

There were 91 responses to the 350 letters. The responses yielded 31 sibling pairs of presumed affected subjects and presumed unaffected siblings, aged 6 to 27 years. Eighteen of these pairs were excluded for the following reasons: the presumed affected sibling was initially referred for a learning disability (5 pairs); at least one sibling had a neurologic disorder, such as epilepsy or optic glioma (6 pairs); one or both siblings were unavailable during the study period (2 pairs); a diagnosis of NF1 could not be confirmed in the presumed affected sibling (2 pairs); or the presumed unaffected sibling had one or more café au lait spots (3 pairs). The remaining 13 pairs of siblings formed the sample for this pilot study.

Table 2 gives the clinical features of the 13 sibling pairs. The affected member of each pair is listed first. Abbreviated pedigrees indicate the status of first-degree relatives with respect to NF1 and developmental disabilities. Seven sibling pairs were of the same sex. With the exception of the siblings of pair 5, who were black American, all sibling pairs were white. The affected

Table 1.—Definition of Developmental Disabilities		
Diagnostic Category	Test or Rating Instrument	Diagnostic Criteria or Threshold
Low cognitive function	Wechsler Intelligence Scale for Children—Revised (WISC-R) ¹² and Wechsler Adult Intelligence Scale—Revised (WAIS-R) ¹³	Full-scale IQ <80: 70-79 indicates borderline mental retardation; 50-69, mild mental retardation
Spoken language disorder	Boston Naming Test, ¹⁴ Clinical Evaluation of Language Function, ¹⁵ and Token Test ¹⁶	>1 SD below mean for age
Reading disability (dyslexia)	WISC-R or WAIS-R, Gray Oral Reading Test (GOR), ¹⁷ Wide-Range Achievement Test (WRAT), ¹⁸ and Grade Equivalent Reading Level	Full-scale IQ 80-114, reading scores not at grade level, and reading quotient (RQ) <80 (RQ indicates reading age* divided by mental age); or Full-scale IQ ≥115 and RQ <80 (RQ indicates reading age divided by chronologic age)
Other learning disability	WRAT—Math and WRAT—Spelling	Math quotient (MQ) or spelling quotient (SQ) <0.80 (MQ or SQ as for RQ above)
Attention-deficit disorder	Examiner's Rating, Conner's Rating Scale for Parents, ¹⁹ Halstead-Reitan Trails, A/B Subtest, ²⁰ Digits Forward for Age, Digits Backward for Age, Cancellation of Repeated Target Symbols, and Performance Tests "592" and "LIF" ²¹	Four or more "fail-for-age" points (range, 0-9 points)† as sum of failures across ratings and tests

*Reading age was derived from the mean of GOR and WRAT, unless GOR was at or above the expected grade-equivalent reading level, in which case the GOR value was used as the reading age.

†Point range is as follows: Examiner's Rating, 0-1; Parent's Rating, 0-2; Trails, 0-1 for each of two tests; Digits Forward, 0-1; Digits Backward, 0-1; "592," 0-1; and "LIF," 0-1. This definition, developed for research purposes, is more stringent in its addition of assessment observations than are *DSM-III* or *DSM-III-R* criteria and was based on consultations with Judith Rapoport, MD, Chief, Child Psychiatry Branch, National Institute of Mental Health, Bethesda, Md.

member of pair 7 had had pseudoarthrosis of the tibia, and the affected member of pair 12 had asymmetry of the jaw. The head circumference of the affected siblings tended to be large; it was at or above the 90th percentile in 8 of the subjects. Only in pair 8 was the head circumference of the unaffected sibling relatively larger than that of the affected sibling. Probable or possible developmental disabilities, including non-right-handedness,²⁵ were present in first-degree relatives without neurofibromatosis in 10 of the 13 families.

There was a significant difference ($P<.0001$, Wilcoxon's Signed Rank Test) in the mean total score (\pm SD) on the PANESS between affected subjects (21.5 ± 12.3) and controls (5.6 ± 3.6), with a median of 16 and 5, respectively (Figure). On average, affected subjects showed more abnormalities than controls on all five sections of the examination, but motor abnormalities involving station, balance, and gait accounted for nearly two thirds of the total score of the affected subjects.

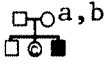

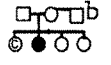

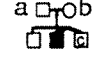

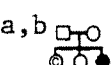

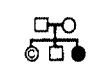

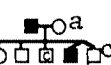

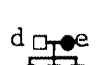

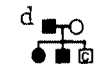

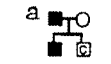

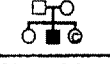

There was also a significant difference ($P<.0001$, Wilcoxon's Signed Rank Test) in mean full-scale IQ

score (\pm SD) between affected subjects (93.9 ± 11.7) and controls (105 ± 13.8), with a median of 96 and 104, respectively (Figure). The IQ scores of the affected subjects were not clustered in the subnormal range but tended to be slightly but consistently shifted downward compared with the scores of the unaffected siblings. With the exception of pair 1, the controls scored higher than the affected subjects on the verbal and performance IQ test (Table 2). The affected sibling of pair 1 was a 10-year-old boy with mathematical skills in the normal range, but his 16-year-old unaffected sister met the criteria for a specific learning disability in mathematics.

Five of the affected subjects underwent CT scanning of the brain. The affected member of pair 9, who scored the highest for neurologic abnormalities, had a normal CT scan, and none of the other scans showed changes suggestive of a tumor or dilated ventricles.²⁶

Only one of the three measures of neuropsychologic function distinguished affected subjects from controls, namely, the Iowa Judgment of Line Orientation Test. In this test of visual-spa-

*Non-R indicates non-right-handed; ADD, attention-deficit disorder; OLD (M,S), other learning disorder (mathematics and spelling); and SLD, spoken language disorder. For family history (pedigree), a solid square or circle indicates an affected person, and a c within a square or circle indicates a control subject; an a indicates non-R; b, possible dyslexia; c, possible ADD; d, OLD; and e, probable dyslexia. Pair 4 includes fraternal twins. Parent employment codes are as follows: 1 indicates professional and 7, laborer.

†In axillary or inguinal areas.

‡Question mark indicates an inconclusive examination.

Subtle neurologic disability and full-scale IQ in 13 subjects with neurofibromatosis type 1 (Recklinghausen's disease) and 13 unaffected sibling controls. Solid symbols indicate affected subjects; open symbols, unaffected subjects; squares, males; and circles, females. Number in relation to symbol is the number of the sibling pair as listed in Table 2. Vertical axis on the left is the neurologic disability score, as determined by total number of points on the Physical and Neurological Examination for Subtle Signs⁹ of developmental neurologic abnormalities.

tial ability, the subject predicts the angle that would be produced if two separate lines were to intersect. The test was performed by the nine sibling pairs who were at least 8 years old, the minimum age for which the test is normalized. Eight affected subjects and one unaffected subject scored in the deficient range ($P < .025$, McNemar's Symmetry Test plus correction factor), and one affected subject scored in the superior range.

Actual or suspected developmental disabilities involving cognitive function were found in 10 affected subjects and 8 controls (Table 2). The affected subjects had no apparent excess of low cognitive function, specific learning disorders, or attention-deficit disorder compared with their sibling controls. Because most learning disabilities show a male preponderance,²⁶ we inspected the results for males with NF1 and male controls. Among the 10 males with NF1, there were 2 subjects with dyslexia, 5 subjects with other learning disorders, and 3 subjects with possible attention-deficit disorder. Among 4 male controls,

there was 1 subject with dyslexia, 3 with other learning disorders, and 1 with attention-deficit disorder.

COMMENT

Reduced cognitive function did not seem to be present in either of the two subjects described in Von Recklinghausen's original report.²⁷ About subject 1, he commented, "Apart from a great attraction to the male sex, she exhibited nothing unusual in her mental sphere"; and of subject 2, he noted, "His intelligence did not seem exceptional, nor on the other hand below average." Subsequent reports, however, often mentioned an association between Recklinghausen's disease and reduced cognitive function.

In the extensive Michigan study,⁴ in which patients with neurofibromatosis were ascertained from multiple medical sources, a mean IQ of 45 was found in 20 institutionalized patients compared with a mean IQ of 77 in 15 of 203 noninstitutionalized patients for whom such data were available. In patients with neurofibromatosis ascertained through Australian hospitals,³ mental retardation was reported in 11 (14%) of 78 children. A later study⁷ suggested that other developmental disabilities are also common in this disorder.

A review of previous studies showed one or more of the following limitations: (1) minimal criteria for the diagnosis of NF1 were not stated, and subjects with other conditions sharing some features of this form of neurofibromatosis, such as bilateral acoustic neurofibromatosis (NF2), may have been included; (2) the presence of a focal neurologic process that could produce a selective neurologic or cognitive defect was not ruled out; (3) the selection of subjects was probably biased toward those with neurologic and cognitive handicaps since, in most studies, subjects were ascertained through hospitals rather than population sampling; and (4) the results of subjects were compared with historical values from the general population rather than with results from concurrent controls, without regard to social and environmental factors that can influence intelligence and educational achievement.²⁸

Perhaps because the current study specifically addressed the limitations of

previous studies, it was able to identify consistent neurologic and cognitive alterations in NF1. In addition, because the study was conducted at one center, all 13 sibling pairs were assessed by the same investigators. Nevertheless, our study has its limitations, one of which is the likelihood of bias in ascertaining families with suitable sibling pairs. Subjects were recruited by a letter describing the neurologic and neuropsychologic focus of the study, and families with children perceived to have problems in these realms may have been more likely than others to respond. To overcome this tendency, we excluded the five subjects in whom evaluation for a developmental disability led to the diagnosis of NF1. Also, some controls who had no clinical signs or symptoms of the disease may still carry the NF1 gene, which will become manifest later; however, in a previous survey,²⁹ all affected children exhibited some skin manifestations by age 5 years.

Another possible criticism of our study is that an intracranial mass or other focal neurologic process could have been missed in any of the eight subjects with NF1 who did undergo CT scanning. Furthermore, neuropsychologic testing took as long as 2½ hours, which required considerable motivation of the subjects, particularly for the young ones and those with attention-deficit disorder. Still, the tester had 10 years of experience in testing young age groups.

It is also possible that the developmental disabilities in our study occurred to excess in the relatives who did not have NF1. If NF1 is associated with developmental disability and if assortative mating for such dysfunction exists, developmentally disabled persons may be more likely to mate with other developmentally disabled persons. However, our use of sibling controls with the same biologic parents as affected subjects should permit distinction between developmental disabilities resulting from familial influences and those attributable to the NF1 gene itself.

A final limitation of our study is the small sample size. Because of the rigorous selection criteria, only 13 sibling pairs from the initial sample of 31 pairs were tested. Thus, only large differences would achieve statistical signifi-

cance. In each sibling pair, the affected member had more neurologic abnormalities than did the unaffected member. The abnormalities were subtle and chiefly involved axial coordination, station, and gait. The instrument employed, the PANESS, did not discriminate absolutely between affected and unaffected subjects, since some unaffected ones had a slightly higher examination score than some with NF1. Although the significance of subtle neurologic signs involving voluntary movements has been debated,³⁰ their reproducibility has recently been validated,³¹ and their usefulness as predictors of such neurologic disorders as Huntington's disease has been demonstrated.³²

Although the mean full-scale IQ score was significantly lower in the siblings with NF1, a specific cognitive deficit did not seem to be a factor. However, affected males tended to score higher on the performance IQ scale than on the verbal IQ scale (seven scored higher, one scored lower, and one scored equal on both scales). In addition, the neurologic assessment score did not predict the full-scale IQ score for affected subjects.

Alteration in visual-spatial function may be a feature of NF1, and one with clinical consequences. This finding was the only major neuropsychologic abnormality in our study and was also in a recent study of children attending a learning disorders clinic,³³ in which related test instruments demonstrated visual-motor disability in 12 (56%) of 23 children with NF1 but in only 18 (6%) of 297 clinic controls.

Although certain neurologic deficiencies and one specific cognitive deficit were characteristic of NF1, the affected subjects had no significant excess of cognitive developmental disabilities (Table 1) compared with their unaffected siblings. Of the 10 affected siblings who had one or more developmental disabilities, 6 were not right-handed. Of the 13 unaffected siblings, 2 were not right-handed and 8 had one or more developmental disabilities. In all, 30 of 64 persons in these 13 families had clinical evidence of developmental disabilities. This frequency appears high, but addi-

tional studies are needed for clarification. There also does not seem to be a specific developmental disability that is characteristic of NF1.

What underlies the mild but consistent neurologic and cognitive alterations? The one relevant study,³⁴ an autopsy report, compared the brains from 10 adults with NF1 and 5 controls. Some brains from those with NF1 had abnormal collections or nests of neurons deep in the white matter, as well as distorted cortical architecture with polymicrogyria and abnormal cortical layering, perhaps resulting from abnormal migration of precursor neuronal cells from the neural crest. Further evidence for widespread alteration of the brain in NF1 comes from the observation of our study and others⁶ that head circumference is often increased.

Mary Ann Wilson, chapter president, and the members of the Metropolitan Washington Chapter of the National Neurofibromatosis Foundation encouraged this study and participated in it, and Kenneth Rosenbaum, MD, provided the families who were attending the Neurofibromatosis Clinic at Children's Hospital National Medical Center. B. J. Hessie and Carolyn Collins provided editorial assistance.

BUILDING BLOCKS FOR CHILDREN'S HEALTH

Connaught DTP Vaccine

(Diphtheria and Tetanus Toxoids
and Pertussis Vaccine, Adsorbed, USP)

Dedicated to the research, development, manufacture and distribution of vaccines and biologicals, Connaught Laboratories ensures a consistently high level of product quality and purity while maintaining a competitive price in the marketplace. Connaught DTP Vaccine — quality built upon product and service.

ALSO AVAILABLE:

Diphtheria and Tetanus
Toxoids Adsorbed USP (DT)

Connaught DTP Vaccine

(Diphtheria and Tetanus Toxoids and Pertussis Vaccine, Adsorbed, USP)

BRIEF SUMMARY

Before prescribing, please consult the complete package circular.

INDICATIONS AND USAGE: For active immunization of infants and children to age 7 years against diphtheria, tetanus and pertussis (whooping cough) simultaneously. DTP is recommended for primary immunization of infants and children up to 7 years of age. However, in instances where the pertussis vaccine component is contraindicated, or where the physician decides that pertussis vaccine is not to be administered, Diphtheria and Tetanus Toxoids Adsorbed (For Pediatric Use) should be used. Immunization should be started at 6 weeks to 2 months of age and be completed before the seventh birthday.

CONTRAINDICATIONS: Persons 7 years of age and older must NOT be immunized with Pertussis Vaccine.

Absolute contraindications.

1. Allergic hypersensitivity to any component of the vaccine.
2. Fever of 40.5°C (105°F) or greater within 48 hours.
3. Collapse or shock-like state (hypotonic-hyporesponsive episode) within 48 hours.
4. Persisting, inconsolable crying lasting 3 hours or more or an unusual, high-pitched cry occurring within 48 hours.
5. Convulsion(s) with or without fever occurring within 7 days.
6. Encephalopathy occurring within 7 days; this includes severe alterations in consciousness with generalized or focal neurologic signs.

The presence of a neurologic condition characterized by changing developmental or neurologic findings, regardless of whether a definitive diagnosis has been made, is also considered an absolute contraindication to receipt of pertussis vaccine, because administration of DTP may coincide with or possibly even aggravate manifestations of the disease. Such disorders include uncontrolled epilepsy, infantile spasms, and progressive encephalopathy.

Use of this product is also contraindicated if the child has a personal or family history of a seizure disorder. However, the ACIP does not accept family histories of convulsions or other central nervous system disorders as contraindications to pertussis vaccination.

IT IS ALSO A CONTRAINDICATION TO ADMINISTER DTP TO INDIVIDUALS KNOWN TO BE SENSITIVE TO THIMEROSAL. IN ANY CASE, EPINEPHRINE INJECTION (1:1000) MUST BE IMMEDIATELY AVAILABLE SHOULD AN ACUTE ANAPHYLACTIC REACTION OCCUR DUE TO ANY COMPONENT OF THE VACCINE.

Elective immunization procedures should be deferred during an outbreak of poliomyelitis.

WARNINGS: This vaccine must NOT be used for immunizing persons 7 years of age and older.

IMMUNIZATION SHOULD BE DEFERRED DURING THE COURSE OF ANY ACUTE ILLNESS. THE OCCURRENCE OF ANY TYPE OF NEUROLOGICAL SYMPTOMS OR SIGNS, INCLUDING ONE OR MORE CONVULSIONS (SEIZURES) FOLLOWING ADMINISTRATION OF THIS PRODUCT IS AN ABSOLUTE CONTRAINDICATION TO FURTHER USE. USE OF THIS PRODUCT IS ALSO CONTRAINDICATED IF THE CHILD HAS A PERSONAL OR FAMILY HISTORY OF A SEIZURE DISORDER.

THE PRESENCE OF ANY EVOLVING OR CHANGING DISORDER AFFECTING THE CENTRAL NERVOUS SYSTEM IS A CONTRAINDICATION TO ADMINISTRATION OF DTP REGARDLESS OF WHETHER THE SUSPECTED NEUROLOGICAL DISORDER IS ASSOCIATED WITH OCCURRENCE OF SEIZURE ACTIVITY OF ANY TYPE.

The administration of DTP to children with proven or suspected underlying neurological disorders, must be decided on an individual basis. Please refer to ACIP recommendations for the following categories of patients:

1. Infants as yet unimmunized who are suspected of having underlying neurologic disease.
2. Infants and children with neurologic events temporally associated with DTP.
3. Incompletely immunized children with neurologic events occurring between doses.
4. Infants and children with stable neurologic conditions.
5. Children with resolved or corrected neurologic disorders.

Immunosuppressive therapies, including irradiation, antimetabolites, alkylating agents, cytotoxic drugs, and corticosteroids (used in greater than physiologic doses), may reduce the immune response to vaccines. Short-term (less than 2 weeks) corticosteroid therapy or intra-articular, bursal, or tendon injections with corticosteroids should not be immunosuppressive. Although no specific studies with pertussis vaccine are available, if immunosuppressive therapy will be discontinued shortly, it would be reasonable to defer immunization until the patient has been off therapy for one month, otherwise, the patient should be vaccinated while still on therapy.

Persons receiving immunosuppressive therapy, a recent injection of immune globulin, or having an immunodeficiency disorder, may not generate an adequate immunologic response to the DTP vaccine.

DTP should not be given to infants or children with any coagulation disorder that would contraindicate intramuscular injection, unless the potential benefit clearly outweighs the risk of administration.

The simultaneous administration of DTP, oral polio virus vaccine (OPV), and/or measles-mumps-rubella vaccine (MMR) has resulted in seroconversion rates and rates of side effects similar to those observed when the vaccines are administered separately. Please refer to ACIP recommendations.

PRECAUTIONS

GENERAL

Epinephrine injection (1:1000) must be immediately available should an acute anaphylactic reaction occur due to any component of the vaccine.

Prior to an injection of any vaccine, all known precautions should be taken to prevent side reactions. This includes a review of the patient's history with respect to possible sensitivity and any previous adverse reactions to the vaccine or similar vaccines (see CONTRAINDICATIONS), and a current knowledge of the literature concerning the use of the vaccine under consideration.

The vial of vaccine should be vigorously shaken to ensure a proper suspension of the antigen and adjuvant.

Special care should be taken to ensure that the injection does not enter a blood vessel.

A separate sterile syringe and needle or a sterile disposable unit should be used for each individual patient to prevent transmission of hepatitis or other infectious agents from one person to another.

ADVERSE REACTIONS

Not all adverse events following administration of DTP are causally related to DTP vaccine.

Adverse reactions which may be local and include pain, erythema, heat, edema and induration with or without tenderness, are common after the administration of vaccines containing diphtheria, tetanus, or pertussis antigens. Some data suggest that febrile reactions are more likely to occur in those who have experienced such responses after prior doses. However, these observations were not noted by Barkin, R.M., et al. Occasionally, a nodule may be palpable at the injection site of adsorbed products for several weeks. Sterile abscesses at the site of injection have been reported (6-10 per million doses).

Mild systemic reactions, such as fever, drowsiness, fretfulness, and anorexia, occur quite frequently. These reactions are significantly more common following DTP than following DT, are usually self-limited, and need no therapy other than, perhaps, symptomatic treatment (e.g., antipyretics). Rash, allergic reactions, and respiratory difficulties, including apnea, have been observed.

Moderate to severe systemic events, such as fever of 40.5°C (105°F) or higher, persistent, inconsolable crying lasting 3 hours or more, unusual high-pitched crying, collapse, or convulsions, occur relatively infrequently. More severe neurologic complications, such as a prolonged convulsion or an encephalopathy, occasionally fatal, have been reported to be associated with DTP administration.

Approximate rates for adverse events following receipt of DTP vaccine (regardless of dose number in the series) are indicated in Table 1.

TABLE 1. Adverse events occurring within 48 hours of DTP immunizations

Event	Frequency*
Local	
Redness	1/3 doses
Swelling	2/5 doses
Pain	1/2 doses
Mild/moderate systemic	
Fever >38°C (100.4°F)	1/2 doses
Drowsiness	1/3 doses
Fretfulness	1/2 doses
Vomiting	1/15 doses
Anorexia	1/5 doses
More serious systemic	
Persistent, inconsolable crying (duration ≥3 hours)	1/100 doses
High-pitched, unusual cry	1/900 doses
Fever ≥40.5°C (≥105°F)	1/330 doses
Collapse (hypotonic-hyporesponsive episode)	1/1,750 doses
Convulsions (with or without fever)	1/1,750 doses
Acute encephalopathy†	1/110,000 doses
Permanent neurologic deficit†	1/310,000 doses

*Number of adverse events per total number of doses regardless of dose number in DTP series. †Occurring within 7 days of DTP immunization.

The frequency of local reactions and fever following DTP vaccination is significantly higher with increasing numbers of doses of DTP, while other mild to moderate systemic reactions (e.g., fretfulness, vomiting) are significantly less frequent. If local redness of 2.5 cm or greater occurs, the likelihood of recurrence after another DTP dose increases significantly.

Although there are uncertainties in the reported studies, recent data suggest that infants and young children who have had previous convulsions (whether febrile or nonfebrile) are more likely to have seizures following DTP than those without such histories.

Rarely, an anaphylactic reaction (i.e., hives, swelling of the mouth, difficulty breathing, hypotension, or shock) has been reported after receiving preparations containing diphtheria, tetanus, and/or pertussis antigens.

Sudden infant death syndrome (SIDS) has occurred in infants following administration of DTP. A large case-control study of SIDS in the United States showed that receipt of DTP was not causally related to SIDS. It should be recognized that the first three primary immunizing doses of DTP are usually administered to infants 2-6 months old and that approximately 85% of SIDS cases occur at ages 1-6 months, with the peak incidence occurring at 6 weeks-4 months of age. By chance alone, some SIDS victims can be expected to have recently received vaccine.

Onset of infantile spasms has occurred in infants who have recently received DTP or DT. Analysis of data from the NCEs on children with infantile spasms showed that receipt of DTP or DT was not causally related to infantile spasms. The incidence of onset of infantile spasms increases at 3-9 months of age, the time period in which the second and third doses of DTP are generally given. Therefore, some cases of infantile spasms can be expected to be related by chance alone to recent receipt of DTP.

Reporting of Adverse Events

Reporting by parents and patients of all adverse events occurring within 4 weeks of antigen administration should be encouraged.

The following illnesses have been reported as temporally associated with the vaccine; neurological complications including cochlear lesion, brachial plexus neuropathies, paralysis of the radial nerve, paralysis of the recurrent nerve, accommodation paresis, and EEG disturbances with encephalopathy. In the differential diagnosis of polyradiculoneuropathies following administration of a vaccine containing tetanus toxoid, tetanus toxoid should be considered as a possible etiology.

Radiological Case of the Month

Margaret Ann L. Co, MD; Ingrid K. Rosner, MD; Yahya M. Berkmen, MD;
Irwin Rappaport, MD (*Contributors*); Beverly P. Wood, MD (*Section Editor*)

A 10-year-old girl was brought to the pediatric emergency department after a falling 120 × 240-cm sheet rock pinned her chest against a wall. She complained of chest pain and coughed up a teaspoonful of bright-red sputum. Her respiratory rate was 22/min. She

had no fever or cyanosis. The physical examination was remarkable only for mild ecchymosis and costochondral tenderness over the right infraclavicular region and decreased breath sounds over the anterior right upper portion of the chest. Her history and family history were normal. Her growth and development were normal. She has always resided in New York City, with the exception of a 1-month visit to Ecuador 6 years earlier. There was no known exposure to tuberculosis or other infection.

A chest roentgenogram was obtained in the emergency department

(Fig 1) and a computed tomographic examination was performed the following day (Fig 2). Results of a complete blood cell count and arterial blood gas and liver function test results were normal. Creatine phosphokinase level was initially elevated to 275 U/L (100% CK-MM). Purified protein derivative was nonreactive, but her father developed a 20-mm induration in 48 hours. The father's chest roentgenogram was normal. Sputum or blood cultures yielded no pathogens. No acid-fast bacilli were found in bronchial washings and none grew in the subsequent cultures.

Accepted for publication October 20, 1988.

Figure 1.

Denouement and Discussion

Traumatic Pulmonary Pseudocyst

Fig 1.—Two cavities (C) and surrounding areas of increased density are present in the right upper lobe. The wall of the larger and medially located cavity is mostly thin (arrow). The inner surfaces of the cavities are smooth.

Fig 2.—Top, Computed tomographic scan at the level of the aortic arch shows two cavities (C) in the right upper lobe surrounded by consolidated lung parenchyma. Mottled consolidation throughout the right upper lobe represents pulmonary contusion. Arrows indicate a small anterior pneumothorax. Bottom, Section at the right upper lobe bronchus (B) shows perihilar and posterior pulmonary parenchymal contusion and hemorrhage. Note a medially located small pneumothorax (arrow).

Fig 3.—Follow-up chest roentgenogram obtained 10 weeks later is normal.

Cavitary pulmonary lesions may result from blunt chest trauma. They are variably named pseudocysts, pseudocystic hematoma, traumatic cysts, pneumatocele, and traumatic lung cavities.¹ *Traumatic pulmonary pseudocyst* is the most widely accepted term. Eighty-five percent of reported cases occur in patients under age 30 years.^{2,3}

Patients present with mild symptoms following blunt chest trauma. Symptoms last 1 or 2 days and consist of cough and chest pain. Hemoptysis occurs in about 40% of the patients^{1,2} and is usually mild. In some cases, marked hemoptysis coinciding with evacuation of the cyst can occur. Low fever and leukocytosis have been reported and are probably related to lung injury and resorption of the hematoma.

Traumatic pseudocysts result from laceration of the lung parenchyma with elastic recoil pull acting centrifugally on the damaged lung and leakage of air from alveoli or torn bronchi-

oles.^{2,3} The resiliency of the thorax in young people is thought to be one of the most important factors contributing to the formation of traumatic lung cysts. It is theorized that the chest is rapidly compressed, then rapidly reexpands, with a decrease in the intrathoracic pressure. This effect may burst or shear the lung.³

While the clinical picture is innocuous, the radiologic findings are striking. A cavitary lesion develops quickly, and an air-fluid level is frequently present. There is usually pulmonary consolidation surrounding the cavity, producing the false appearance of a thick wall. If the cavity is completely filled with blood, a homogeneous density is seen,⁴ but the cavitary nature of the lesion becomes evident after hemoptysis and evacuation of the cyst contents. Spontaneous resolution usually occurs within 1 to 3 weeks. Cyst superinfection is reported and presents with purulent sputum, increasing pulmonary consolidation, fever, and leukocytosis.²

The roentgenographic appearance of traumatic pseudocyst may suggest lung abscess or cavitation secondary

to tuberculosis or fungal infection. Congenital adenomatoid malformation or a bronchogenic cyst may be included in the differential diagnosis. A history of recent chest trauma in an otherwise-healthy person, negative or normal skin tests and cultures, and comparison with previous chest roentgenograms are usually sufficient to exclude these possibilities. Spontaneous resolution of the lesion(s) within a few weeks further supports the diagnosis.

Traumatic pulmonary pseudocyst requires no specific treatment. Prophylactic administration of antibiotics is disputed in light of the rare occurrence of secondary infection. Surgical intervention is reserved for cases of persistent infection or significant ventilatory compromise secondary to large pseudocysts.⁵

In our patient, there was complete radiologic resolution of the cyst and absence of any clinical symptoms 10 weeks after the injury (Fig 3). Pulmonary function tests at that time revealed a decrease in diffusing capacity for carbon monoxide, suggesting related residual alveolar capillary disruption.

Figure 3.

Denouement and Discussion

Fig 1.—*Loxosceles reclusa*, the brown recluse spider.

Fig 2.—Bite of the brown recluse spider with local pustule, erythema, and induration.

Fig 3.—Typical bite of the brown recluse spider with local cyanotic pustule and necrosis.

The brown recluse is a medium-sized spider with rather long legs that cover an area of about the size of a quarter to a half-dollar (Fig 1). The legs and body are covered with fine hairs, and it is light to tawny brown. Most spiders have eight eyes; however, the brown recluse has only six eyes. Another distinguishing characteristic is the dark violin or fiddle-shaped marking directly above the legs on the cephalothorax.

In the United States, there are 13 species of spiders belonging to the genus *Loxosceles*. The bite of at least 4 species—*Loxosceles reclusa*, *Loxosceles deserta*, *Loxosceles laeta*, and *Loxosceles rufescens*—is associated with systemic reactions in humans. The species *L. reclusa*, commonly called the brown recluse spider, violin spider, or fiddleback spider, is by far the species most commonly associated with human bites. It inhabits many southern and midwestern states, in-

cluding Alabama, Arkansas, Georgia, Kansas, Kentucky, Louisiana, Mississippi, Missouri, Nebraska, Ohio, Oklahoma, Tennessee, and Texas.

The brown recluse is a shy, solitary spider and clusters in favorable habitats, such as under the loose bark of standing dead trees. In the home, they can be found in cellars, closets, basements, bedrooms, and bathrooms, and behind pictures, wall hangings, curtains, furniture, and appliances.

The bite of the brown recluse varies from a stinging or burning sensation to a severe systemic condition and even death. Most bites are located on the buttocks, upper thigh, or foot. They produce local pain and pruritus during the first 24 hours, and systemic signs, if they occur, are evident within 72 hours (Fig 2). The bite may become a cyanotic pustule and progress to a necrotic eschar with stellate ulceration (Fig 3). Systemic loxoscelism may be more common in children and pro-

duces a scarlatiniform rash, generalized urticaria, malaise, and fever. In some cases, vomiting and diarrhea, disseminated intravascular coagulation, shock, and death can occur. The differential diagnosis of spider bites includes bites and stings from other arthropods and insects, cellulitis, vasculitis, and pyoderma gangrenosum.

The treatment of brown recluse spider bites remains controversial. Early and delayed surgical excision, intralesional steroids, systemic steroids such as oral prednisone, ice or cold packs applied to the bite, aspirin, oral antibiotics, tetanus toxoid, and even antivenin have all been tried. Most recently, oral dapsone, an inhibitor of neutrophil function, has been used to treat severe *Loxosceles* bites.

Pulse Oximetry in Methemoglobinemia

Mehernoor F. Watcha, MD, DCh; Michael T. Connor, MD; Anne V. Hing, MD

• Pulse oximetry is a major improvement in the assessment of oxygenation. The device uses plethysmography and light absorbance measurements at two wavelengths to estimate oxygen saturation. It is inaccurate, however, when more than two types of hemoglobin are present. This article describes two infants with methemoglobinemia in whom pulse oximetry overestimated oxygen saturation. We discuss the mechanism of this systematic error and emphasize that pulse oximetry should not be used to estimate true oxygen saturation in the presence of methemoglobin. However, a disparity between oxygen saturation estimates by pulse oximetry and by calculations based on the arterial partial pressure of oxygen and the oxygen-hemoglobin dissociation curve can provide an important clue to the presence of such abnormal types of hemoglobins. Therapy should be based on direct measurements of oxyhemoglobin by cooximetry and not on measurements of oxygen saturation by pulse oximetry or on saturations calculated from the P_{aO_2} and the oxyhemoglobin dissociation curve.

(AJDC. 1989;143:845-847)

Pulse oximetry is a major advance in the noninvasive monitoring of oxygen saturation. It has been quickly accepted in clinical practice because it is easy to perform, painless, rapid in response, and accurate when arterial saturations are greater than 65%.^{1,2} Unlike transcutaneous oxygen tension measurements, pulse oximetry requires no warm-up time, special skin preparation, or complex calibration. However, pulse oximetry gives an inaccurate estimate of arterial oxygen saturation (SaO_2) in the presence of dyes,³⁻⁶ abnormal types of

hemoglobins,⁷⁻¹¹ or when the saturation is below 65%.^{1,2} In this article, we describe two infants with severe acquired methemoglobinemia whose SaO_2 level was measured by pulse oximetry and cooximetry (which measured the oxyhemoglobin [HbO_2] level) and calculated from the P_{aO_2} measurements.

PATIENT REPORTS

PATIENT 1.—A 12-month-old male infant was brought to a community hospital after his mother saw an older sibling feeding him phenazopyridine hydrochloride (Pyridium) tablets, a urinary analgesic known to cause methemoglobinemia.¹² The neonate was awake, alert, and comfortable, and had normal vital signs. His nail beds and lips were cyanotic. He was treated with Ipecac, activated charcoal, and magnesium sulfate. An arterial blood sample was brown, did not change color on exposure to air, and had a methemoglobin concentration of 16%. The child then received 1.5 mg/kg of methylene blue intravenously, but 30 minutes later on arrival at St Louis (Mo) Children's Hospital, he was still cyanotic and comfortable. Another arterial blood sample was obtained, and additional methylene blue (2 mg/kg) was administered, with resolution of the cyanosis. The patient was discharged after an uneventful 48-hour hospitalization. Serial arterial blood gas analysis results, pulse oximetry readings, and HbO_2 and methemoglobin values are given in Table 1.

PATIENT 2.—A 3-week-old female neonate was admitted to St Louis Children's Hospital with a 4-day history of diarrhea, vomiting, and irritability. She was grunting and tachypneic. Her fontanelle was sunken, and her hands and feet were cold. Skin turgor and capillary refill improved after vigorous fluid resuscitation. An arterial blood sample was obtained at this point, and the results are given in Table 1 along with pulse oximetry readings. Although the P_{aO_2} level was 166 mm Hg, her blood was dark, and the SaO_2 value was only 78%. Methemoglobinemia was suspected and confirmed by cooximetry. Methylene blue (1 mg/kg) was administered intravenously. We failed to identify exposure to nitrites, nitrates, benzocaine, dyes,

or other agents known to produce methemoglobinemia.¹² Blood, urine, stool, and cerebrospinal fluid cultures did not reveal pathogens. Results of hemoglobin electrophoresis and determinations of erythrocyte glucose-6-phosphate dehydrogenase and urine amino acids were within normal limits. Urine organic acid screening revealed only lactic acid. Urine drug screens disclosed only those medications administered by health care personnel after hospital admission. Diarrhea recurred with refeeding, and poor weight gain persisted despite the administration of a monosaccharide, protein hydrolysate formula. On the 10th day, severe grunting Kussmaul respiration occurred, and methemoglobin concentrations were again elevated. Despite vigorous therapy with intravenous fluids, methylene blue, antibiotics, as well as catecholamines, tracheal intubation, and ventilation, the child lost all evidence of cerebral function and died on the 16th day. Values for arterial blood gas, cooximetry, and pulse oximetry are presented in Table 1.

COMMENT

Oxygen saturation can be directly measured by a cooximeter using spectrophotometric techniques to estimate the HbO_2 percentage of total hemoglobin concentration in a blood sample. These values are expressed either as a percentage of total hemoglobin concentration (reduced hemoglobin level + HbO_2 level + carboxyhemoglobin level + methemoglobin level) or as a percentage of hemoglobin concentration that has a capacity to bind to oxygen (HbO_2 level + reduced hemoglobin level). The former value is termed *fractional oxygen saturation* and the latter, *functional oxygen saturation*. In this article, all HbO_2 values represent the fractional oxygen saturation.

In the typical clinical blood gas laboratory, oxygen saturations are usually not measured directly but are calculated from P_{aO_2} levels and the oxygen-hemoglobin dissociation curve as corrected for the effects of temperature,

*Fio₂ indicates fraction of inspired oxygen; Sao₂, arterial oxygen saturation using pulse oximetry; Hbo₂, oxyhemoglobin percentage of total hemoglobin concentration; Hb, hemoglobin; and MethHb, methemoglobin.

†Saturation of Hb calculated from the Pao₂ value and the oxygen-hemoglobin dissociation curve.

Paco₂ levels, hematocrit, and 2,3-diphosphoglycerate activity.¹⁸ Calculated oxygen saturations assume the presence of only HbO₂ or reduced hemoglobin.

In clinical situations, pulse oximetry has an advantage over these intermittent laboratory measurements, as it permits the continuous noninvasive monitoring of oxygen saturation in vivo. Although pulse oximetry has substantially improved the treatment of patients at risk for hypoxia, it has its limitations. The accuracy of pulse oximetry can be affected by patient movement,^{1,14} compression of the sensor,^{1,2,14} severe desaturation,² low perfusion states,^{1,11,14} surgical electrocautery,^{11,14} infrared heating lamps,^{1,2,7,11,14} nail polish (other than red),¹⁵ intravenous dyes,^{8,6} and abnormal types of hemoglobins.^{8,11,16}

Oxygen saturation measurements derived from pulse oximetry and cooximetry are based on Beer's law, which states that the concentration of a solute in suspension has an exponential relationship to the intensity of light that is transmitted through it.^{1,2,17} The cooximeter (IL-282) measures light absorbance at four wavelengths and uses the extinction coefficients at each wavelength to calculate the relative concentrations of HbO₂, reduced hemoglobin, carboxyhemoglobin, and methemoglobin. The pulse oximeter employs only

two wavelengths and identifies the influx of arterial blood by plethysmography. The "pulse added" absorbance signal exceeding diastolic tissue absorbance is measured at 660 and 940 nm, and the ratio is calculated by a microprocessor in the device. This ratio has been empirically correlated with oxygen saturation values obtained from invasive data in healthy adult volunteers. A ratio of 3.4, 1.0, and 0.43 correlates with oxygen saturation readings of 0%, 85%, and 100%, respectively.^{1,10,11,17} An increase in the 660- to 940-nm light absorbance ratio is interpreted by the pulse oximeter as a fall in oxygen saturation.

Pulse oximetry (Sao₂) values are not affected by differences in skin pigmentation, total hemoglobin concentration, or thickness of the tissue at the site of monitoring.^{1,2,7,11,17} However, the two-wavelength system does not allow the device to differentiate between more than two types of hemoglobin (HbO₂ and reduced hemoglobin). If another form of hemoglobin is present, pulse oximetry readings may correlate poorly with cooximetry values of HbO₂.^{7,8} In carbon monoxide poisoning, pulse oximetry gives higher readings than the true HbO₂ levels by cooximetry and consequently fails to alert the physician to potentially lethal hypoxia.⁸

Theoretical considerations suggest

Table 2.—Extinction Coefficients of Hemoglobin Derivatives*

Wavelength	660 nm	940 nm
Oxyhemoglobin (adult)	0.08	0.30
Reduced hemoglobin (adult)	0.8	0.20
Carboxyhemoglobin	0.07	0.02
Methemoglobin	0.81	0.64
Fetal oxyhemoglobin	0.09	0.34
Fetal reduced hemoglobin	0.91	0.20

*Optical density of an absorber in a concentration of 1 mmol/L measured with a path length of 1 cm.

that methemoglobin will also affect Sao₂ readings. Methemoglobin is formed by converting iron in hemoglobin to the ferric state in which it cannot bind to oxygen. This form of hemoglobin absorbs more light at both 660 and 940 nm than does HbO₂ or reduced hemoglobin but has a disproportionately greater absorbance at 660 nm (Table 2). The result, an increase in the 660- to 940-nm absorbance ratio, is interpreted by the pulse oximeter as a reduction in oxygen saturation. When 65% or more of the total hemoglobin concentration is in the methemoglobin form, the 660- to 940-nm light absorbance ratio approaches 1.27. This generates an Sao₂ reading of 75% to 80%, even though the maximum possible HbO₂ value is 35%. Therefore, the pulse oximeter progressively overestimates oxygen saturation with increasing methemoglobin concentrations and will not warn the clinician that a dangerous hypoxic state is developing.

These predictions were confirmed in our patients. In patient 1, as the methemoglobin concentration dropped from 54.8% to 15.2%, the HbO₂ level rose in proportion, but the Sao₂ values remained between 63% to 86% (Table 1). Pulse oximetry readings were greater than the HbO₂ levels until therapy decreased the methemoglobin concentrations to 5.6%. When methemoglobin concentrations are below 10% and the oxygen tensions are high, the remaining 90% of hemoglobin may be completely saturated with oxygen to give an HbO₂ value of 90%. This concentration of methemoglobin will cause an increase in the 660- to 940-nm ratio so that the Sao₂ reading is 91%, a fortuitous correlation with the HbO₂ level.^{10,11,16,17} However, if

the nonmethemoglobin fraction contains both HbO₂ and reduced hemoglobin, the SaO₂ values will be higher than the HbO₂ values.¹⁷

In both patients, the low SaO₂ readings in the presence of high PaO₂ values and calculated saturations suggested the presence of an abnormal type of hemoglobin. Transcutaneous oxygen monitoring provides values that reflect PaO₂ values and may be normal in the presence of severe methemoglobinemia.¹⁸ Oxygen saturation calculated from the arterial or transcutaneous oxygen tension values will provide a false sense of security, as these calculations are based on the assumption that all hemoglobin has the capacity to bind to oxygen. Since

methemoglobin has no oxygen-carrying capacity, the patient with methemoglobinemia is at risk for tissue hypoxia even if the PaO₂ value is high.^{9,10,12,16,18}

Methylene blue is known to have a dose-dependent artifactual effect on both HbO₂ and SaO₂ readings. This effect is transient and lasts for less than 30 minutes at the doses used in clinical practice.^{3,6} Since blood samples for cooximetry were drawn more than an hour after the administration of methylene blue in our patients, the differences between the low SaO₂ and HbO₂ readings cannot be explained by this artifactual effect.

A disparity between the oxygen saturation calculated from PaO₂ values and

pulse oximetry readings can be an important clue to the presence of methemoglobinemia. In these patients, pulse oximetry overestimates oxygen saturation and should not be used to reflect arterial oxygen content or tissue oxygen delivery. Therapy should be guided by direct measurements of HbO₂ and methemoglobin using a cooximeter and not on the basis of measurements using pulse oximetry or on estimates of calculated oxygen saturation.

We thank the nurses of the Pediatric Intensive Care Unit at St Louis Children's Hospital who provided the care for these patients. We also gratefully acknowledge the secretarial assistance of M. Bicknell.

Toxic Shock Syndrome Caused by a Strain of *Staphylococcus aureus* That Produces Enterotoxin C but Not Toxic Shock Syndrome Toxin-1

Munir F. Rizkallah, MD; Asad Tolaymat, MD; Jose S. Martinez, MD; Patrick M. Schlievert, PhD; Elia M. Ayoub, MD

• An 8-month-old infant presented with pneumonia and pleural effusion associated with clinical manifestation of toxic shock syndrome. A *Staphylococcus aureus* strain isolated from the pleural fluid produced enterotoxin C, but not toxic shock syndrome toxin-1 or other enterotoxins. Acute and convalescent sera showed an antibody rise to enterotoxin C but not to toxic shock syndrome toxin-1. These findings support the possibility that enterotoxin C was the primary toxin associated with this infant's illness.

(AJDC. 1989;143:848-849)

Toxic shock syndrome (TSS) was first described in seven children by Todd et al¹ in 1978. Two years later, TSS was reported to occur primarily among healthy menstruating women, particularly those using high-absorbency tampons.^{2,3} A more recent update indicated that the syndrome occurs in men and nonmenstruating women, too, and that the proportion of nonmenstrual cases may be increasing.⁴

In 1981, a toxin responsible for TSS was identified independently by Schlievert et al⁵ and Bergdoll and colleagues.⁶ Called TSS toxin-1 (TSST-1), this toxin was produced by more than 90% of staphylococcal strains isolated from menstruating patients. In addition to TSST-1, enterotoxin B has primarily been associated with nonmenstrual TSS.^{4,7} Staphylococcal enterotoxin C was first isolated from an adult patient in whom

the two staphylococcal isolates produced enterotoxin C and TSST-1.⁸ Another report describes a "variant" TSS in a neonate born to a mother with TSS associated with enterotoxin C.⁹

Toxic shock syndrome is rare in infancy and there have been, to our knowledge, only two confirmed occurrences of TSS in children under 1 year of age.^{10,11} In this report we describe TSS in an 8-month-old child associated with *Staphylococcus aureus* producing enterotoxin C, but not TSST-1 or other enterotoxins.

REPORT OF A CASE

An 8-month-old boy was seen in the emergency department for respiratory distress and diarrhea. He was irritable, had a temperature of 41°C, a pulse rate of 195 beats per minute, and a respiratory rate of 60 to 80/min. He had conjunctival hyperemia with oral mucosal ulcerations, fissured lips, and excoriating diaper rash with scabbed lesions over the legs. Intercoastal and subcostal retractions were noted with decreased breath sounds over the right lung field.

Laboratory tests indicated a hemoglobin level of 110 g/L, a hematocrit of 0.33, and a white blood cell count of 9.5×10^6 /L with 0.43 polymorphonuclear leukocytes, 0.29 band forms, 0.22 lymphocytes, and 0.06 monocytes. Platelet count was 75×10^6 /L. Prothrombin time was 12 seconds, with control of 9 seconds; partial thromboplastin time was 51 seconds, with a control of 32 seconds. Fibrinogen level was 5.3 g/L. Blood urea nitrogen level was 6.5 mmol/L of urea with a creatinine level of 90 μ mol/L. Serum glutamic-pyruvic transaminase level was 88 IU/dL. Throat culture yielded normal flora. Cerebrospinal fluid and blood cultures were negative. There was no serologic evidence of leptospirosis. Chest roentgenogram showed a right lower lobe consolidation with pleural effusion.

Within 12 hours of admission, the patient

developed erythroderma of the palms, soles, perineum, and lips. The systolic blood pressure dropped to 64 mm Hg, requiring aggressive fluid replacement with Ringer's lactate solution (40 mL/kg of body weight), and plasmanate (20 mL/kg), in addition to dopamine hydrochloride.

After the pleural effusion was drained, parenteral treatment with nafcillin sodium and gentamicin sulfate was begun. Three days after admission, a fine desquamation of the skin was noted over the palms, soles, and perineum. There was no exfoliation of the skin in other areas nor was there any Nikolsky sign. The patient's respiratory status gradually improved, diarrhea subsided, and he was weaned off dopamine on the fifth hospital day, when his cardiovascular status stabilized. He received nafcillin for 21 days along with gentamicin for the first week. The patient was seen 10 weeks after hospital discharge and was doing well.

Staphylococcus aureus was isolated from the pleural effusion. When the organism was examined for toxin production, staphylococcal enterotoxin C was identified, but not TSST-1¹² or other enterotoxins. In addition, serologic tests demonstrated that the patient mounted an antibody response to enterotoxin C, with an acute serum antibody titer of 1:10 and convalescent titer (3 weeks later) of 1:320.¹³ In contrast, the serum titer against TSST-1 was 1:20 in both acute and convalescent samples.

COMMENT

Toxic shock syndrome is an acute multisystem disease characterized by high fever, hypotension, gastrointestinal symptoms, and an erythematous rash.^{1,3} The diagnosis of TSS in the patient described in this report was based on the clinical manifestations, which included a high fever and a diffuse erythematous rash associated with conjunctival hyperemia. Other pertinent signs included hypotension and evi-

dence of disseminated intravascular coagulation. There was also evidence for involvement of the liver, gastrointestinal tract, lungs, and central nervous system. *Staphylococcus aureus* was isolated from the pleural fluid.

Although more than 90% of vaginal TSS *S aureus* strains produce TSST-1, only 50% to 60% of *S aureus* isolates obtained from other sites in cases of nonmenstrual TSS produce TSST-1.^{4,7} In addition, the production of staphylococcal enterotoxins by TSS-associated strains of *S aureus* is significantly increased over that of non-TSS strains, notably enterotoxin B.^{4,7} As illustrated by the patient described in this report, the *S aureus* isolated from the empyema fluid produced enterotoxin C but not TSST-1 or other enterotoxins. This enterotoxin has been shown to produce in primates many signs and symptoms similar to those observed in TSS in humans.¹⁴ The toxin shows a highly significant sequence homology with enterotoxin B.¹⁵

Green and LaPeter¹⁶ and Chow et al⁹ described two neonates with TSS resulting from possible intrapartum transmission. Chow et al⁹ have reported in 1984 a variant postpartum TSS with probable intrapartum transmission to the neonate due to *S aureus* producing enterotoxin C but not TSST-1. Toxic shock syndrome developed in both mother and infant despite preexisting high antibody titers to TSST and enterotoxin C. Nonmenstrual cases of TSS in children have been associated with skin infections after surgical procedures,¹⁰ abscesses,¹¹ tracheitis,¹⁷ empyema,¹⁸ adenitis,¹⁹ other or unknown sources of infection.¹⁰

The presence of *S aureus* producing TSS-associated toxins and the absence of antibody to the toxins in acute-phase sera have been considered as markers of

TSS.^{6,8} Elevated levels of anti-TSST-1 in acute-phase serum would be highly unlikely. So, in a patient with suspected TSS, in addition to examining the *S aureus* isolate for the ability to produce TSST-1 or enterotoxins, acute and convalescent sera should be tested for antibody against the toxins. Recent reports have described the association of TSS with *Staphylococcus hyicus* and with group A streptococcus.^{20,21} Of note is that the *S hyicus* elaborated TSST-1. Another study has shown that the group A streptococcal exotoxin possesses immunologic cross-reactivity with staphylococcal enterotoxin B and C1.²²

The patient described in this report is, to our knowledge, one of the youngest described as having TSS. The other unusual feature about this patient is that the *S aureus* isolated produced enterotoxin C but not TSST-1 or other enterotoxins. With the apparent increase in nonmenstrual patients with TSS, this disease should be suspected even in young children with sudden onset of fever, shock, diarrhea, rash, and evidence of multisystem illness associated with a staphylococcal infection.

Alternating Sequential Dosing With Furosemide and Ethacrynic Acid in Drug Tolerance in the Newborn

Sylvain Chemtob, MD, PhD, FRCPC; Jean-Luc Doray, MD, FRCPC; Nicole Laudignon, MD; Apostolos Papageorgiou, MD, FRCPC; Daya R. Varma, MD, PhD; Jacob V. Aranda, MD, PhD, FRCPC

• Drug tolerance seems to develop rapidly after the administration of sequential doses of the same loop diuretic. We evaluated whether alternating different loop diuretics could achieve the same initial diuretic response in the newborn. In a randomized double crossover study, we examined the diuretic and saluretic effects of alternating doses of furosemide and ethacrynic acid (1 mg/kg administered intravenously every 24 hours) in 10 newborns, who received the drugs in the following sequential order: (1) furosemide, (2) ethacrynic acid, and (3) furosemide (group 1, $n=5$); and (1) ethacrynic acid (2) furosemide, and (3) ethacrynic acid (group 2, $n=5$). Hourly urine specimens were collected for the determination of rates of urinary and fractional excretion of sodium, chloride, and potassium and of urinary flow, before and 6 hours after dosing. There were no differences between the groups at each dose for all parameters measured. A significant decrease in pre-diuretic and postdiuretic rates of urinary flow, in sodium and chloride excretion, and in the fractional excretion of these electrolytes was observed before and after dosing. The associated reduction in patients' weights suggested a depletion in plasma volume. In conclusion, consecutive alternation of furosemide and ethacrynic acid in the same newborn does not prevent the development of pharmacologic tolerance to loop diuretics, since diuresis, natriuresis, and chloriuresis decrease after successive sequential administration of these drugs.

(AJDC. 1989;143:850-854)

Accepted for publication January 26, 1989.

From the Department of Neonatal Research and Developmental Pharmacology and Therapeutics, Montreal Children's Hospital and the Sir Mortimer B. Davis Jewish General Hospital, McGill University, Montreal, Canada.

Independent evaluations of furosemide and ethacrynic acid have shown that after administration of single doses, these drugs exert similar diuretic, natriuretic, and saluretic effects in the neonate.¹⁻⁶ However, during long-term administration of these agents, pharmacologic tolerance develops, resulting in a decrease in the diuretic response in both newborns and adults.^{6,7} This desensitization can be overcome in adults by substituting one loop diuretic for another, such as ethacrynic acid for furosemide.^{7,8} The reasons for the efficacy of this substitution may be attributed to differences in their mechanisms of action.⁹⁻¹¹ For instance, in addition to inhibiting renal tubular transport of chloride,⁷ furosemide, but not ethacrynic acid, can inhibit carbonic anhydrase,^{10,11} whereas only ethacrynic acid can inhibit $\text{Na}^+-\text{K}^+-\text{ATPase}$.⁹ To test whether the same initial response could be sustained by alternating furosemide and ethacrynic acid in the newborn, we examined the diuretic and saluretic effects after sequential administration in a randomized double crossover study.

PATIENTS AND METHODS

Patient Population

Newborns were entered in the study after informed consent by their legal guardians. This study was approved by the Sir Mortimer B. Davis Jewish General Hospital Ethics Committee, Montreal, Canada. Ten newborns with similar clinical demographic profiles (Table 1) were randomly assigned to two groups, as described below. The clinical status of the patients was the same in both groups at the time of the study. No patient presented any active medical problem, eg, ventilator or oxygen requirement, patent ductus arteriosus, or metabolic disturbance, during diuretic efficacy assessment. All patients were in a state of normal hydration,

which was maintained by the administration of well-established fluid requirements (130 to 150 mL/kg per day).¹² During the postnatal period (Table 1), major components of renal function, such as inulin clearance and natriuresis, are relatively stable.^{13,14} The newborns were weighed at the beginning of, and every 6 hours during, the study period. Fluid and electrolyte intake was unaltered after the newborns responded to the diuretics. None of the newborns received any concurrent drugs.

Diuretic Administration

The only indication for diuretic administration in all patients occurred after blood transfusion (7 mL/kg of packed red blood cells) for the correction of anemia resulting from iatrogenic blood loss.¹⁵ Administration of one or two doses of diuretics for blood transfusion is an accepted and common practice in our neonatal intensive care unit. The third dose of diuretic was administered for the purposes of the study, as approved by the hospital's ethics committee and after informed consent was given by the legal guardians of the patients. No patients had received diuretics for at least 1 week before entering

*Values are mean ± SD. Diuretics were administered to each group in the following order: group 1, (1) furosemide, (2) ethacrynic acid, and (3) furosemide; group 2, (1) ethacrynic acid, (2) furosemide, and (3) ethacrynic acid.

† $P < .05$ vs the appropriate values before or after the first dose.

the study.

The 10 neonates were randomly assigned to begin receiving either furosemide or ethacrynic acid, after which the diuretics were alternated every 24 hours, for a total of three doses (1 mg/kg per dose administered intravenously). The time interval was chosen to minimize a carryover effect.^{1,3,6} Therefore, the two groups of newborns received the diuretics in the following sequential order: group 1 ($n = 5$), (1) furosemide, (2) ethacrynic acid, and (3) furosemide; group 2 ($n = 5$), (1) ethacrynic acid, (2) furosemide, and (3) ethacrynic acid.

Sample Collection and Measured Variables

Patients were placed on a metabolic bed installed in their isolettes, where urine was collected for the measurement of volume, electrolytes, and creatinine. The aliquots of urine were obtained 6 hours before (predose) and 6 hours after (postdose) the administration of each diuretic dose.^{1,3} Stools were collected separately and discarded.

Serum electrolyte, serum urea nitrogen, and creatinine concentrations were determined before administration of the first diuretic dose and 2 hours after each drug ad-

ministration. These measurements were obtained as part of the routine clinical care and, in part, for the purpose of this study, as approved by our hospital's ethics committee and consented to by the patients' legal guardians.

The above measurements, obtained before and after the administration of each drug dose, were used to calculate urinary flow rates (expressed in milliliters per kilogram per hour); fractional excretions of sodium and of chloride (expressed as a percent of the creatinine clearance); sodium, chloride, and potassium excretion rates (expressed in microequivalents per kilogram per hour); and creatinine clearance (expressed in milliliters per minute per 1.73 m²). Osmolar clearance was not included because of the limited volume of the blood samples.

Statistical Analysis

Data analyses were performed using paired and unpaired Student's *t* tests, one-way ANOVA for repeated measurements, the Mann-Whitney *U* Test, and the Wilcoxon Rank-Sum Test. Due to sample size, non-parametric tests were also performed; the latter confirmed analysis obtained from the parametric tests. The results are expressed

as mean ± SD. Statistical significance was set at $P < .05$.

RESULTS

Pharmacologic Effects of Sequentially Alternating Furosemide and Ethacrynic Acid

The rates of urinary flow, electrolyte excretion, fractional electrolyte excretion, and creatinine clearance, for the 6 hours after administration of the bolus, are presented in Table 2. No differences in rates of urinary flow, excretion or fractional excretion of electrolytes (Table 2, postdose results), or creatinine clearance were found at each dose between groups 1 and 2.

Compared with the effects after the first dose, a decrease in urinary flow was demonstrated in all patients in groups 1 and 2 after the second and third diuretic doses (group 1, $P < .03$; group 2, $P < .04$; Fig 1 and Table 2, postdose values). Sodium and chloride urinary excretion rates ($P < .01$), and the urinary fractional excretion rates of these elec-

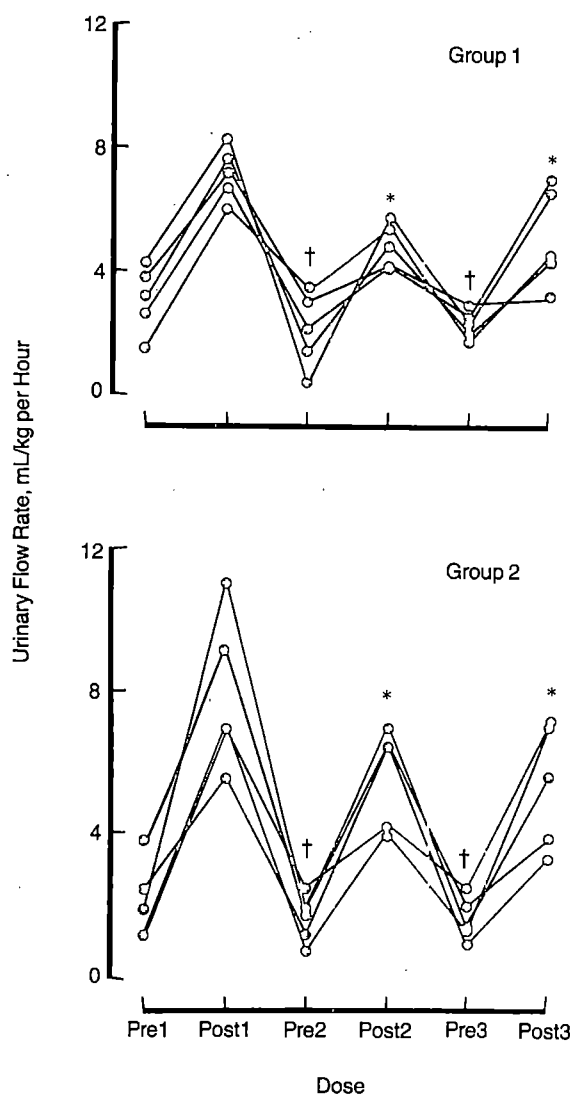

Fig 1.—Urinary flow rate as a function of diuretic dose sequence in each patient. Diuretics (1 mg/kg per dose) were administered intravenously every 24 hours in the following order: group 1, (1) furosemide, (2) ethacrynic acid, and (3) furosemide; group 2, (1) ethacrynic acid, (2) furosemide, and (3) ethacrynic acid. The numbers 1, 2, and 3 on the abscissa refer to the dose order (eg, pre1 indicates before the first dose; post1, after the first dose). The asterisk indicates $P < .05$ vs post1 (Wilcoxon Rank-Sum Test); dagger, $P < .05$ vs pre1 (Wilcoxon Rank-Sum Test).

trolytes ($P < .005$), were also shown to decrease in both groups (Table 2, post-dose values). Potassium excretion rates and urinary creatinine clearance rates did not change in either group of patients. Very similar findings were obtained when responses in the rates of urinary flow, electrolyte excretion, and

fractional excretion of electrolytes for each patient were analyzed as *percent changes from respective predose values*.

To evaluate whether these decreases in diuretic, natriuretic, and chloriuretic responses resulted from a possible decrease in plasma volume, secondary to the diuretic action, we analyzed the *pre-*

diuretic rates of urinary flow, sodium and chloride excretion, and fractional sodium and chloride excretion in both groups. A gradual reduction in these parameters was observed in both groups ($P < .05$; Fig 1 and Table 2, predose values). In addition, there was a slight but significant decrease in the weights of the infants at the end of the experiment. The respective weights before the first dose and after the last dose were as follows: group 1, 1958 ± 116 g and 1851 ± 127 g ($P < .05$); group 2, 2149 ± 137 g and 2064 ± 118 g ($P < .05$). This reduction in rates of *prediuretic* urinary flow, urinary fractional excretion, and sodium and chloride excretion after the first drug dose suggested a diminished plasma volume.

Serum electrolyte, serum urea nitrogen, and creatinine concentrations remained stable throughout the study, except for a slight decrease in chloride concentration in group 2, from 108.0 ± 0.7 mEq/L to 101.8 ± 2.9 mEq/L ($P < .01$), before the first dose and after the third dose, respectively. Rates of urinary flow, electrolyte excretion, and fractional electrolyte excretion did not correlate with birth weight or with gestational, postnatal, or postconceptional age, as previously observed.^{1,3}

Relationship Between the Pharmacodynamic Effects of Furosemide and Ethacrynic Acid, and Correlation of the Effect of the Initial Dose of One Drug With Its Second Dose

Since it is well recognized that there is a great deal of interpatient variability involved in the use of diuretics,^{1-3,7} we assessed whether, in the same patient, the response to the first dose of either drug correlated to that of the second drug (second dose). The groups were combined, since they were very similar in their responses to the diuretics, as previously shown. A significant correlation was only found for the rate of urinary flow ($r = .81$; $P < .01$; Fig 2, second dose vs first dose). When the responses were analyzed as percent changes from baseline, there was again a significant correlation in the rate of urinary flow between the first and second doses ($r = .65$; $P < .01$). These findings suggest that subjects with the greatest diuretic response to the first drug maintained an

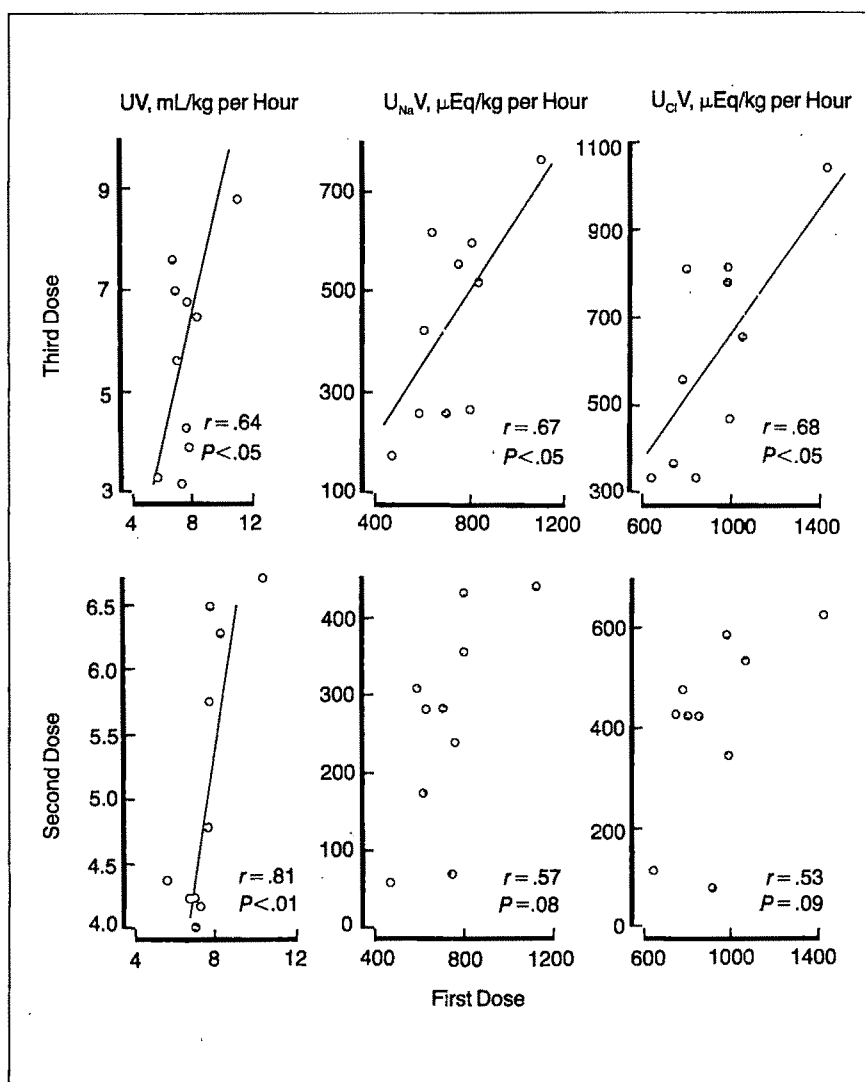

Fig 2.—Relationship of the urinary flow rate (UV) and sodium ($U_{Na}V$) and chloride ($U_{Cl}V$) excretion rates between furosemide and ethacrynic acid (second dose vs first dose, bottom graphs) and between the first and third (ie, the second dose of the first diuretic administered) diuretic doses (top graphs). Regression line is indicated only where a significant relationship ($P < .05$) exists.

enhanced response to the second drug. Similarly, patients with the lowest diuretic response to the first agent continued to respond the least to the second agent. Therefore, the magnitude of response is maintained in the same patient.

We also assessed whether the response to a drug is maintained after its second administration, ie, the third dose. As shown in Fig 2 (third dose vs first dose), a significant correlation was found for rates of urinary flow ($r = .64$) and sodium ($r = .67$), chloride ($r = .68$), and potassium ($r = .84$; latter not shown) excretion ($P < .05$). These corre-

lations were also observed when responses were analyzed on the basis of percent change. Thus, the subject's qualitative response to the same agent is maintained; patients with the greatest response maintained the same high response, and those with the lowest response continued to respond the least to the same drug.

COMMENT

The aim of this study was to determine whether the development of pharmacologic tolerance to a single diuretic administered over an extended period^{6,7} can be avoided by alternating consecu-

tive doses of furosemide and ethacrynic acid in the newborn. Our data show that despite the alternation of furosemide and ethacrynic acid during consecutive drug doses, there is a decrease in diuresis, natriuresis, and chlориuresis after the initial dose of either of these diuretics. The results are comparable with those observed in two studies of the long-term administration of furosemide in newborns and adults.^{6,7} These studies showed that there is a decrease in the pharmacodynamic response to the second and subsequent doses of furosemide relative to the response to the first dose. However, in contrast to findings in the adult, in whom the substitution of ethacrynic acid for furosemide reestablished the response,^{7,8} this result was not observed in the newborn.

Many studies have already shown that tolerance develops after the administration of consecutive doses of loop diuretics in both the newborn and the adult.^{6,7,16} We therefore did not think that it was ethically justified to replicate these studies and to subject our patients to parallel experiments using the same agent repeatedly, to enable within-study comparison. From a clinical point of view, our results had clearly demonstrated that switching loop diuretics in the newborn failed to avoid the rapidly developing pharmacologic tolerance to a single drug. If tolerance may partly result from a reduction in plasma volume,^{6,7,16} it is possible that other patient populations with fluid overload states, such as infants with bronchopulmonary dysplasia, may not respond more favorably to alternate sequential doses of furosemide and ethacrynic acid.⁶

The possible mechanisms of this tolerance to consecutive doses of loop diuretics were not examined in this study, and remain to be explored. However, certain inferences may be speculated from our data. We have observed a decrease in *prediuretic* rates of urinary flow, fractional excretion, and excretion of sodium and chloride (Fig 1 and Table 2, predose values). These decreases, which were associated with the decrease in patients' weights, were suggestive of a diminished plasma volume, possibly contributing to this rapid development of tolerance, as previously proposed in the adult.^{7,16} Although prediuretic creatinine clearance had not de-

creased after the first dose of either drug, this parameter of measure of glomerular filtration rate has limitations in the newborn,^{17,18} in contrast to the more accurate but more invasive inulin clearance.^{18,19} Furthermore, mild volume depletion, initially not associated with changes in glomerular filtration, leads to increased proximal tubular reabsorption of fluid.²⁰ Consequently, regardless of the glomerular filtration rate, proximal tubular reabsorption may be enhanced; therefore, less sodium and chloride are delivered to the site of action of the loop diuretics.⁷

Recent findings indicate that decreased extracellular fluid volume seems to be the cause of tolerance to loop diuretics.^{7,16} Reversal of this tolerance by the substitution of loop diuretics in the adult⁷ may result from their effects at different sites of action.⁸ In contrast, tolerance to diuretics in the newborn, despite the alternation of consecutive doses of these agents, persists, perhaps because in younger subjects there is a relative lack of efficacy of diuretics on other sites of action, com-

pared with their principal one. This, however, needs to be evaluated.

The significant correlations in diuresis found between repetitive doses of the same drug (first dose vs third dose) and between the two different drugs (first dose vs second dose) imply that the magnitude of response is maintained in the same subject. Hence, newborns with better responses or those with lower responses preserve their ability to respond, regardless of the agent subsequently administered. The findings are consistent with each individual's physiologic capability to balance sodium concentration and fluid volume.⁷ These data imply that the continued administration of loop diuretics in an infant who is not adequately responding to the first dose may not achieve therapeutic objectives but may accumulate and produce toxicity.²¹ We have found a consistent, although statistically nonsignificant, increase in urinary electrolyte excretion and fractional excretion of sodium and chloride after the third diuretic dose, without further changes in urinary output (Table 2,

postdose results). In addition, a concomitant decrease in serum chloride concentration was observed. These findings are in accord with the clinical observation that chronic dosing can lead to adverse effects by causing ongoing losses of electrolytes despite a reduced urinary output.

In conclusion, alternating sequential administration of furosemide and ethacrynic acid in the newborn infant does not prevent the development of pharmacologic tolerance to these drugs. Future investigations using combined diuretics that clearly act at separate tubular sites may reveal advantages to this type of therapy.²² Such pharmacologic approaches may improve therapeutic response in patients who require long-term diuretic treatment, such as preterm infants with bronchopulmonary dysplasia.

This study was supported in part by the Medical Research Council of Canada and the McGill University Montreal Children's Hospital Research Institute.

Prescription of Psychotropics to Children in Office-Based Practice

Kelly J. Kelleher, MD, MPH; Ann A. Hohmann, PhD, MPH; Dave B. Larson, MD, MSPH

• Multiple authors have stressed the need for close follow-up and simultaneous psychotherapy in most children treated with psychotropic drugs. However, little is known about the actual prescription of psychotropic medications in pediatric settings. Using the 1985 National Ambulatory Medical Care Survey, we investigated the frequency of follow-up arrangements and concurrent psychotherapy among US children in visits to office-based practices. We then explored determinants of psychotropic drug prescriptions. Mental health indicators, sociodemographic characteristics, provider type, and provider familiarity with the patient were important predictors of psychotropic prescriptions. Few providers report referral or concurrent psychotherapy for their patients receiving psychotropics, and follow-up plans were no different for children with or without psychotropics after controlling for other variables. This means that many children in outpatient care who are taking psychotropic medications may not be receiving optimal management for behavioral or emotional problems.

(AJDC. 1989;143:855-859)

Psychotropic drug prescription patterns are "an extremely important issue in health and social policy"¹ research because of these drugs' relatively high cost, frequent potential for addiction or habituation, possible interactions with other drugs, and serious implications for the long-term growth and

cognition of children.²⁻⁴ Numerous articles have recently reviewed and revised the indications for psychotropic drug use in the management of outpatient pediatric mental disorders and symptoms.^{2,4,6} These studies suggest the need for frequent follow-up of children receiving psychotropic medications and the importance of simultaneous psychotherapy in the majority of pediatric behavioral and emotional disorders. However, little is known about the actual prescription of psychotropic medications in pediatric health care settings.

National and community studies on the prescription of drugs in ambulatory pediatric settings have focused primarily on the most frequent medications and classes of medications prescribed, usually antibiotics.^{7,8} These studies have not discussed the frequency of use or factors associated with the use of psychotropic drugs.

Studies that do focus on psychotropic drug prescriptions have used surveys of students and teachers, not physicians, to identify the frequency of psychotropic medication use among US children.⁹⁻¹¹ These studies have usually discussed stimulant medications for hyperactivity and attention-deficit disorder.

Little information has been published on prescription practices for this class of drugs in ambulatory pediatric care in the United States by psychiatrists or primary care providers. The few studies of children treated with psychotropics report that stimulants are the predominant form of pharmacologic therapy in school-based populations^{5,11} and that psychotropics may be underutilized in children referred for mental health problems.¹² Unfortunately, these findings are limited by small sample sizes, recall problems and potential sampling bias. In addition, they do not address

concurrent psychotherapy or follow-up planning by physicians for children receiving psychotropic drugs. We believe it is important to know what psychotropic drugs physicians are prescribing and how they are treating these children.

Using the 1985 National Ambulatory Medical Care Survey (NAMCS), a national probability survey of patient visits to office-based practices, we summarize the prescription of psychotropic drugs to children and adolescents in the United States by patient and provider characteristics. Among children receiving psychotropic or stimulant prescriptions, we assess the following: (1) frequency of follow-up arrangements, (2) frequency of concurrent psychotherapy, and (3) characteristics of patients and providers as reported by psychiatrists and primary care physicians. Finally, we explore the determinants of psychotropic drug prescriptions during office-based visits for ambulatory medical care. We hypothesize that mental health indicators, sociodemographic factors, and type of health care provider will be important determinants of psychotropic drug prescriptions in office-based practice.

METHODS

Sample and Analysis Strategy

The 1985 NAMCS is a national sample of patient records from office-based physicians engaged in patient care activities, as defined by the American Medical Association and American Osteopathic Association.¹³ The data were collected by the National Center for Health Statistics (NCHS) and include 71 594 records of patient visits to 2879 physicians from a sample of 4104 physicians, a response rate of 70.2%; 12 320 visits were by patients less than 18 years of age. There was a national estimated total of 138 255 812 visits by patients less than 18 years of age in 1985. For this analysis, all children who had missing drug prescription data ($n=186$) were eliminated.

Accepted for publication January 11, 1989.

The NCHS used a multistage probability design for the 1985 NAMCS: Counties or Standard Metropolitan Statistical Areas were stratified by size, region, and demographic characteristics. Physicians within areas were stratified by specialty. Physicians were selected by an NCHS allocation formula (details are available from the NCHS). Finally, patient visits were randomly selected from all visits to selected physicians in one randomly chosen week of the year. Actual data collection was performed by the physician, aided by office staff.

Because selection was not completely random and because the NCHS wanted to be able to provide national estimates of office visits, the NCHS assigned each visit a weight. The weight corrects for the design effect of a stratified complex sample so that the sample population may be used to estimate the total number of national visits to office-based practices and to estimate appropriate SDs for the sample. The base population used to compute annual visit rates is derived from estimates by the US Bureau of the Census of the civilian, noninstitutionalized population as of July 1, 1985. Because of the design effect, it is important to report both the actual number of pediatric visits as well as the nationally based weighted percentage. Standard deviations and confidence intervals are based on the weighted proportions. For differences between proportions, SEs were estimated, confidence intervals were constructed for each proportion, and a determination was made as to whether the intervals (95% or 99%) overlapped. Children who were prescribed at least one psychotropic medication were compared with children not receiving psychotropics on sociodemographic factors, provider type, familiarity with the provider, psychiatric recognition factors, and follow-up plans. Subsequently, children receiving stimulant medications were compared with children not receiving psychotropics by use of the same variables.

To determine the factors associated with receipt of psychotropic medication during a pediatric visit, a logistic regression model was estimated. A logistic regression analysis was performed for two reasons: (1) The effects of each variable can be examined independently. (2) An analysis of group differences using confidence intervals is extremely conservative. Logistic regression provides single-degree-of-freedom tests for trend that are more powerful than tests of the null hypothesis in bivariate analyses.¹⁴

The statistic presented in a logistic regression is the odds ratio. An odds ratio greater than 1 signifies a greater-than-average risk of receiving a psychotropic prescription. An odds ratio less than 1 signifies a below-average risk. An odds ratio equal to 1 signifies average risk and is considered not sig-

nificant.

Since the exact NCHS sampling probabilities are not published, multivariate analyses of these data cannot take advantage of the computer programs used to adjust for non-random sampling. However, to ignore the weights in the analysis would underestimate the SE estimates, and to use the weights would inflate the sample size into the millions, making all variables significant. Therefore, following the method of Lee et al,¹⁵ each weight was divided by the average weight for the total sample. Thus, the original pediatric sample size and the NCHS weights were retained. The most statistically parsimonious model is presented in the results (ie, the model contains only significant odds ratios or those significantly >1).

Measures

Mental Health Indicators.—The three indicators used to designate a mental health visit were psychiatric reason for visit, psychiatric diagnosis, and psychotherapy. Psychotropic drug prescription was not included as an indicator of a visit for mental health purposes since it was the dependent variable of interest.

The dependent variable was prescription of psychotropic drugs in ambulatory care. Prescription refers to the ordering or providing of a psychotropic drug by a physician and does not take into account patient compliance with physician instruction. Psychotropic drugs are the agents named by physicians in the 1985 NAMCS that had been designated as psychotropic by the NCHS and subdivided into anti-anxiety, antidepressant, and anti-psychotic agents. A further category, stimulants, was added for this study of children. Physicians were instructed to report both new and continued medications in the survey.

Because some patients received psychotropic drugs for physical conditions not related to mental health problems, the NCHS developed a list of non-mental health diagnoses for which psychotropic drugs are indicated in adult populations. Certain diagnoses germane to pediatric practice were added to that list (eg, vomiting and phenothiazines, primary enuresis and tricyclics, leukemia and phenothiazines, and epilepsy and barbiturates), and any visits for these conditions were excluded from further analyses, although these cases accounted for only a few visits.

Reasons for visit were recorded by physicians using the NCHS Reasons for Visit Classification Tabular List. Psychiatric reasons for visits include mental disorders, symptoms referable to psychological and mental disorders, psychiatric examinations, psychotherapy or counseling, and some symptoms referable to the nervous system.

Diagnoses were coded by physicians using the *International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM)*.¹⁶ Psychiatric diagnoses used in this study include ICD-9-CM 290.00 through 319.00.

On the NCHS form, physicians were specifically asked whether a visit included psychotherapy or counseling. This question was used as the indicator of whether psychotherapy was provided.

The disposition of visit was also listed as a separate question, with planned visits or telephone calls considered "scheduled follow-up," while no planned follow-up and return visits as needed were considered "no follow-up planned." Referrals and admissions to hospitals or other dispositions were considered separately.

Sociodemographic Factors.—Age was coded into four levels of 0 to 3, 4 to 8, 9 to 13, and 14 to 17 years. These divisions reflect various developmental stages during which changes in behavior and emotional disorders can be expected, and, therefore, might have an impact on physician prescribing practices.

Race and gender were also included in the regression model because prescribing patterns vary by gender, and race has been associated with differential receipt of other health services. The primary source of payment as recorded was also compared, for the same reasons. All of the above were specific questions on the NAMCS form. Finally, because prescription of psychotropic drugs is frequently inappropriate on a first visit in an office-based setting, patient status (returning patient vs new patient) and the payment method for visits were included.

Provider Type.—Physician specialty was collapsed into five categories: (1) pediatrics, (2) psychiatry (child and other), (3) primary care (family practitioners and general practice), (4) internal medicine, and (5) other (including pediatric subspecialists).

RESULTS

In this study of pediatric visits to physicians in ambulatory medical care settings, 1.5% of the visits by children included the prescription of a psychotropic drug that met the study criteria. The physicians prescribing those drugs had widely divergent prescription patterns. Table 1 shows rates of psychotropic prescriptions per 100 000 visits based on NCHS estimates from the US Bureau of the Census from 1985. Psychiatrists more frequently prescribed a psychotropic drug during a visit than physicians in any of the other medical specialties and are the primary prescribers of stimulants, although the rate

Table 1.—Rates of Prescription of Psychotropic Drugs to Children

Prescribing Physician	No. of Visits	Prescription Rate (per 100 000 Visits) by Drug Type*			
		Anxiolytic	Antidepressant	Antipsychotic	Stimulant
General or family practitioner	3237	730	50	90	120
Pediatrician	4513	310	50	30	140
Internist	250	500	3280	400	90
Psychiatrist	204	1300	6520	7050	10750
All others	4116	750	190	110	130

*These rates are based on the proportion of pediatric visits (weighted to the national estimates of yearly visits) to each provider during which a psychotropic drug of the type specified was given.

for psychiatrists is based on a small number of actual visits ($n = 204$). However, even among those physicians who can be considered primary care physicians (pediatricians, general and family practitioners, and internists), for whom presenting symptoms and diagnoses could be similar, there are marked differences in prescribing patterns. Pediatricians are the least likely to prescribe psychotropics and internists the most likely. Pediatricians and general and family practitioners are more likely to prescribe anxiolytics than any other psychotropic agent, and internists more frequently prescribed antidepressants.

Table 2 presents the demographic

characteristics by drug prescription status of the patients making pediatric visits. Only the age of the patient is significantly associated with whether a psychotropic prescription was given. Children 0 to 3 years of age were significantly less likely to receive a psychotropic prescription than other children, and children 13 to 17 years old were significantly more likely to receive a prescription.

Because of the small number of children receiving stimulants, tests of significance showed no difference between children receiving stimulants and those who received no psychotropic drugs. However, 4- to 8-year-old children and

boys more frequently received stimulants during office visits. Children 0 to 3 years old received no stimulants in this sample.

Table 3 presents the clinical characteristics of the children. Children who received psychotropic drugs and those who received a prescription for stimulants had been seen previously for the same problem significantly more often. New patients or returning patients with new problems were much less likely to receive psychotropic drug prescriptions.

Recognition of a psychiatric condition and physician management plans were powerful predictors of prescription of psychotropic drugs. A psychiatric diagnosis and the reason for visit both predicted receipt of psychotropics of any type. Children who received some type of psychiatric counseling were also more likely to receive psychotropic drugs. Before controlling for other variables, physicians who gave psychotropic prescriptions were more likely to have specified some plan of follow-up with the child. The children who did not receive a prescription were more likely than those who did to have been given no specific follow-up plan.

In Table 4, psychiatric diagnoses, psychotherapy, and follow-up among children receiving psychotropic drugs are presented. Approximately one fifth of children who were prescribed psychotropics received psychotherapy, follow-up, and a psychiatric diagnosis in their visit. One third received either psychotherapy and follow-up plans or a specific psychiatric diagnosis and follow-up plans in addition to psychotropic prescriptions.

The logistic regression model in Table 5 presents the most statistically powerful variables predicting prescription of psychotropic drugs to children in ambulatory medical care settings. Adjusting for all significant factors, the children who are most likely to receive a psychotropic drug prescription are those who are given a psychiatric diagnosis, present with a psychiatric reason for visit, are boys, or are returning to the physician with a previous complaint. Children least likely to receive a psychotropic prescription are those under the age of 9 years and those seeking care from a pediatrician.

COMMENT

To our knowledge, this is the first national study of psychotropic drug prescriptions in outpatient settings for children. In our study, psychotropics were infrequently prescribed during all primary and specialty care outpatient visits by children. Although psychotropic agents were not often prescribed, we found patient characteristics, mental health indicators, and type of provider to be important predictors of psychotropic drug prescriptions in office-based visits by children. The data also suggest that children who receive psychotropic drug prescriptions may be receiving inadequate follow-up care and are not usually receiving concurrent psychotherapy.

Considerable clinical deviation exists between these findings and standards of

care recommended for children treated with psychotropic drugs,^{16,17} which include close follow-up and simultaneous psychotherapy. Controlling for all statistically significant factors in our analyses, children who were prescribed psychotropic drugs were no more likely to have follow-up than children not receiving psychotropics. Over 26% of the children receiving psychotropic medications were not scheduled for follow-up visits. Possible explanations for the lack of scheduled follow-up among many children for whom psychotropics were prescribed include a reliance by some providers on long-term relationships with families expected to report side effects, failure to record accurately the follow-up status on the survey form, or a failure to appreciate the serious implications and side effects of these drugs. Elucidation of these mechanisms will

require provider-specific research.

Besides failing to specify follow-up for many children treated with psychotropic drugs, providers usually did not report psychotherapy for these patients. Although receipt of psychotherapy was associated with psychotropic drug prescriptions, only 36.2% of children given psychotropic medications were provided counseling or psychotherapy during office visits. Less than 22% of children who were prescribed psychotropic drugs in office-based settings received a psychiatric diagnosis, planned follow-up, and counseling or psychotherapy during their ambulatory visit according to providers. Referrals were also rare for children receiving psychotropic drugs in outpatient settings during these visits. Lack of concurrent psychotherapy and insufficient follow-up suggest that many children given psychotropic drugs in outpatient settings are receiving less-than-optimal management.

Because the 1985 NAMCS data are visit-based instead of patient-based and the appropriateness of diagnosis and management by providers cannot be assessed directly, our findings concerning follow-up and concurrent psychotherapy by providers should be interpreted with caution. This is even more important in evaluating rates of psychotropic prescriptions that are uncorrected for confounding factors and severity of illness. Findings on particular subspecial-

Table 5.—Logistic Regression Predicting Prescription of Psychotropic Drugs

	Odds Ratio* (95% Confidence Interval)	P
Psychiatric diagnosis	13.53 (6.44-28.45)	.0000
Psychiatric reason for visit	3.52 (1.63-7.57)	.001
Male	1.46 (1.00-2.14)	.05
Age 0 to 3 y	0.43 (0.25-0.73)	.002
Return patient, same problem	2.11 (1.40-3.17)	.0004
Physician consulted pediatrician	0.61 (0.39-0.95)	.03

*Odds ratios greater than 1 indicate that an individual with a given characteristic (controlling for all other characteristics in the model) has a greater than 50% chance of receiving a psychotropic drug. Odds ratios less than 1 indicate that an individual with a given characteristic has a less than 50% chance of receiving a psychotropic drug. Odds ratios of 1 were eliminated from the model since they show no increased or decreased risk of receiving a prescription for a psychotropic drug (the characteristic does not predict receipt of a prescription).

ties are especially suspect because of the small sample size. Therefore, the estimates of visits per 100 000 population for some subspecialties are likely to be unstable. Another potential source of error is the inability of the NAMCS to account for telephone and renewal prescriptions for psychotropics that are likely to be made without close follow-up or concurrent behavioral counseling. These prescribing behaviors would increase the significance of our findings. On the other hand, ongoing psychotherapy that is known about but not mentioned by the provider is another possible source of error. Additional psychotherapy would decrease the significance of our findings. Multiple psy-

chotropic prescriptions to one child did not affect findings for the regression equation, since all children with at least one psychotropic prescription were considered. However, multiple prescriptions to one child in a visit may have affected the uncorrected estimates of psychotropic prescription rates per 100 000 visits for some specialties with few visits.

Future research to clarify these findings would benefit from a longitudinal design and standardized psychiatric diagnoses. Ideally, provider treatment practices should be studied on a diagnosis-specific basis,¹⁸ using reliable instruments to assess the physical and mental health status of patients. Furthermore,

we recognize the insufficiency of one or several researchers deciding on best-care approaches. Instead, standards of care should be established for prescriptions of psychotropic drugs in pediatric ambulatory care similar to standards of care available now for adult psychiatric patients.¹⁹

In conclusion, we found that mental health indicators, sociodemographic characteristics, provider type, and provider familiarity with the patient were important factors in predicting receipt of psychotropic drugs during ambulatory visits. In addition, few providers report referral or concurrent psychotherapy for their pediatric patients receiving psychotropic medications. After controlling for other variables, follow-up plans were no different for children receiving psychotropics than for those not receiving psychotropic medications. Scheduled follow-up visits and combined treatment approaches using behavioral or cognitive therapy in combination with psychotropic drugs, when indicated, have been repeatedly recommended in the literature for the ambulatory management of most pediatric psychosocial problems. This means that many children in outpatient care taking psychotropic medications may not be receiving optimal management for behavioral or emotional problems.

This work was supported in part by epidemiology training fellowships from the US Public Health Service and the National Institute of Mental Health, Rockville, Md.

Normative Oscillometric Blood Pressure Values in the First 5 Years in an Office Setting

Myung K. Park, MD, Shirley M. Menard, RN, MSN

• We measured blood pressure (BP) and heart rate in 1554 healthy infants and children aged 2 weeks to 5 years using an oscillometric device, to establish normative values in this age group. The BP cuff width was selected to be 40% to 50% of the circumference of the upper arm. Triplicate measurements of BP and heart rate were obtained in the waiting room of pediatricians' offices and well-baby clinics before the patients were examined by the physician or nurse. Three readings were possible in 87% of the infants less than 3 years of age and in all children 3 years of age and older. The average BP value (systolic/diastolic [mean]) increased rapidly from the 2- to 3-week value of 78/47 (59) mm Hg to the 1- to 5-month value of 95/60 (74) mm Hg. No subsequent increase in BP occurred until 2 years of age (96/56 [71] mm Hg) when systolic and mean pressures started to increase at an average annual rate of 2 mm Hg for systolic pressure and 1 mm Hg for mean pressure until reaching the 5-year value of 104/58 (75) mm Hg. Diastolic pressure did not increase from 1 month to 5 years of age. Heart rate decreased with increasing age from the 2- to 3-week value of 153 to the 5-year value of 97 beats per minute. There was no difference in BP and heart rate values between boys and girls or among ethnic groups over the age ranges studied. Considering the high success rate in obtaining BPs in infants and small children, it appears that BP should be determined routinely, regardless of the age of the patients, when an oscillometric device is available.

(AJDC. 1989;143:860-864)

Blood pressure (BP) measurement is an important diagnostic tool in pediatric practice for the early detection of certain disease processes as well as the management of patients with alterations in BP. The conventional auscultatory

BP measurement technique is difficult to apply in newborns, infants, and small children due to faint Korotkoff sounds in these age groups.¹ Recommended methods^{2,3} and normal BP values^{2,3,6-9} have varied widely. Observer-related variation and/or bias may be an important contributor to the wide variation in normative values.^{8,11}

Automated BP measuring devices remove some of the above sources of variation,^{11,12} and an automated oscillometric device has been found to reflect directly measured arterial pressure quite accurately.¹² Of equal importance, they can be applied in the absence of a physician or nurse, thus minimizing environmental effects on BP. These devices are being used with increasing frequency in pediatric patient care areas. However, currently available normative data are derived from several studies in which conventional auscultatory methods or Doppler ultrasonic devices are used. It is necessary to establish normative data for oscillometric devices as well, since both the methodology and the environment for measuring BP differ from those above. It is not known if these differences might yield somewhat dif-

ferent normal values. Therefore, it was the purpose of this study to establish normative BP values for the first 5 years of age by the use of one of these devices, the Dinamap Monitor.

METHODS

The Dinamap Monitor Model 1846 (Critikon Inc, Tampa, Fla) was used in this study. This device detects motions of the BP cuff encircling the extremity. This motion is due to oscillation of the underlying artery. When a cuff inflated to a pressure level above systolic pressure is gradually deflated, three characteristic changes occur in the magnitude of oscillation. A sudden increase in amplitude occurs at systolic pressure, a further maximum increase in amplitude corresponds to mean pressure, and a gradual then sudden decrease in amplitude occurs at diastolic pressure.¹³ The accuracy of this device in reflecting direct arterial pressure has been demonstrated in the neonate,^{14,15} in infants and children,^{12,11} and in adults.¹⁶ The device has an automatic inflation-deflation control that allows multiple measurements without the potential effects of the presence of a physician or nurse and has an optional capability to record BP values.

Infants and children up to 5 years of age who were completely healthy or those who had only minor complaints without fever

Fig 1.—Age-specific percentiles of Dinamap blood pressure values in patients 2 weeks to 5 years of age. The average of three readings is used. Values for 1- to 3-day-old newborns¹⁷ are included for completeness.

were recruited by a research nurse in the waiting room of pediatricians' offices and well-baby clinics in the San Antonio, Tex, area. Some patients were excluded from final analysis based on physicians' findings and diagnoses. Well siblings who accompanied patients were also recruited. Children

known to have cardiac, renal, metabolic, endocrine, neurologic, or pulmonary disease and those taking medications that might affect the BP were excluded from the study. There were a total of 1554 children in the study, including 747 boys (48%) and 807 girls (52%). Of these, 1203 were white (77%), 106

were black (7%), and 245 were Hispanic (16%) (Table 1).

Blood pressure cuffs were selected to be 40% to 50% of the measured circumference of the upper arm of each patient. This cuff size has been shown to permit accurate reflection of intra-arterial BPs in neonates,¹⁴ infants, and children¹² for Dinamap BP measurements. This cuff size coincides with that recommended by the American Heart Association for auscultatory blood pressure determination in children.⁵ To avoid apprehension, the research nurse carried out the blood pressure measurements in the waiting room before the children were seen by a uniformed nurse or physician. Infants were seated in parents' arms, supine on parents' laps, or semireclining in infant seats. Older infants and children were seated beside the parent. Distractions, such as a pacifier or bottle, reading, and talking, were used by the parents or the research nurse to maximize the child's cooperation.

Three BP and heart rate readings were obtained on each child with a 1-minute resting period between readings. Readings on children who became uncooperative or who were called into the examination room during the study were excluded from tabulation. Body weight and height were also recorded whenever available from the physician's office chart. The patient's age, ethnicity, sex, and position (supine, sitting, or semireclining) when BP was measured were recorded for statistical analysis. The statistical analysis was performed using the SPSS X program (SPSS Inc, Chicago, Ill). A one-way ANOVA followed by the Newman-Keuls Test was used when comparing three or more groups. When comparing two groups of data, Student's *t* test was used. Statistical significance was accepted at the .05 level. This study was approved by the Institutional Review Board of the University of Texas Health Science Center, San Antonio, and informed consent was obtained from one parent of each patient.

RESULTS

Sex and ethnicity of the study population are shown for each age group in Table 1. The mean ratio of cuff width to arm circumference (CW/AC ratio) was 0.46 with a range of 0.40 to 0.49. It was possible to obtain three acceptable BP readings in 87% of the infants younger than 3 years of age and in all children 3 years of age and older. Six percent of the children younger than 3 years of age were called into the examination room before the completion of three readings, and 7% of the children younger than 3 years of age did not cooperate enough to permit reliable BP readings.

Fig 2.—Age-specific percentiles of heart rate by Dinamap Monitor in patients 2 weeks to 5 years of age. The average of three readings is used. Values for 1- to 3-day-old newborns¹⁷ are included for completeness.

Table 2.—Differences Between the First Blood Pressure (BP) Reading and the Average of Multiple Readings		
Age Group	Mean \pm SD	
	BP(1)* - XBP(1-2-3)†	BP(1) - XBP(2-3)‡
1 to 11 mo (n=415)		
Systolic	0.66 \pm 8.07	0.99 \pm 12.10
Diastolic	0.86 \pm 7.89	1.29 \pm 11.84
Mean	0.92 \pm 8.05	1.40 \pm 12.09
1 to 5 y (n=1034)		
Systolic	1.71 \pm 6.39§	2.56 \pm 9.59§
Diastolic	1.46 \pm 6.16§	2.19 \pm 9.26§
Mean	1.25 \pm 6.65§	1.88 \pm 9.98§

*BP(1) indicates the first BP readings.

†XBP(1-2-3) indicates the average of triplicate BP readings.

‡XBP(2-3) indicates the average of the second and third BP readings.

§BP(1) is significantly greater ($P < .05$) than XBP(1-2-3) or XBP(2-3).

For each age group, BP and heart rate did not differ between boys and girls ($P > .05$) and among different ethnic groups ($P > .05$). All patients 12 months of age and older and most of the patients 6 to 11 months old (98%) were

sitting when BP was measured. In infants 2 weeks to 5 months of age, BP values were taken with the infant in the sitting position (41.5%), the supine position (24.5%), or a semireclining position (34.0%). There was no statistically sig-

nificant difference in BP among the groups ($P > .50$ for systolic and mean pressures, and $P > .20$ for diastolic pressure). Because sex, ethnicity, and position were not found to contribute significantly to BP and heart rate, data were combined regardless of these variables and were expressed according to age.

Percentile values of the average BP are shown in Fig 1 and those of heart rate in Fig 2. Data from neonates 1 to 3 days old¹⁷ are also included for easier comparison and completeness. There is a rapid rise in systolic, diastolic, and mean pressures between the immediate neonatal period and the 1- to 5-month period (Fig 1). Systolic pressure did not rise from 1 month to 1 year of age. After 1 year of age, it began to increase at a rate of approximately 2 mm Hg per year until 5 years of age. Mean pressure values showed a similar trend to that of systolic pressure, but at a rate of approximately 1 mm Hg per year. Diastolic pressure did not rise from 1 month to 5 years of age (Fig 1).

In general, the first BP readings were greater than the average of the triplicate readings and that of the two latter readings. The average difference between the first reading and the average of the triplicate reading was smaller than the difference between the first and the two latter readings (Table 2). The difference was not statistically different in infants less than 12 months of age ($P > .20$), but was significantly different in children 1 year of age and older ($P < .05$) (Table 2). The correlation between systolic pressure and weight of the patient was fair ($r = .403$, $P < .0001$) and was slightly better than fair with age ($r = .378$, $P < .0001$). The correlation between diastolic ($r = .018$ to $.133$) and mean ($r = .105$ to $.133$) pressures and age, weight, or height was equally poor.

The heart rate decreased with increasing age, except for the immediate neonatal period (Fig 2). The first heart rate was 1 to 2 beats per minute lower than the average of the three readings and the two latter readings in children 3 years of age and older ($P < .05$), but not different in children younger than 3 years old ($P > .05$). There was a good negative correlation between heart rate and age, heart rate and weight, and heart rate and height ($r = .630$ to $-.772$, $P < .0001$).

COMMENT

This study establishes normative BP values in an office setting in infants and small children with the use of the Dinamap Monitor, which is widely used in pediatric patient care areas. A close correlation has been demonstrated between indirect BP values by the Dinamap Monitor and direct arterial BP values in infants and children.¹² There is also indirect evidence that supports the reliability and validity of Dinamap BP values. Systolic BP values in this study are in close agreement with those reported by the 1987 National Institutes of Health (NIH) Task Force,² which were derived from three independent studies using ultrasonic devices (Arteriosonde, Doppler ultrasound probe).

A report of BP values in Japanese children up to 3 years of age using the Arteriosonde is also in close agreement with the results of this study.¹⁸ Diastolic BP values of children 2 to 5 years of age taken as the Korotkoff phase IV reported by the NIH Task Force² agree closely with this study, but the values for infants 1 month to 1 year of age were 4 to 10 mm Hg lower than found by this study, in which the average increments of systolic and diastolic pressure in children 3 years and older were found to be similar to the findings of other epidemiological studies using a sphygmomanometer.^{19,20} In the age ranges studied, there appears to be no sex-related or ethnicity-related differences in BP (or heart rate), which is in agreement with other investigators.¹¹ Although normal BP values found in this study agree with large epidemiological studies,² we need to stress that the data were obtained in an office setting with the selection of patients not strictly adhering to epidemiological principles.

It should be stressed that the oscillometric equipment is merely a different detection device and we should still adhere to well-known guidelines^{1,2,5} of indirect measurement of blood pressure. Correctly selecting and placing the BP cuff on the patient, securing the cooperation of patients, preventing sudden movements of the extremity, and maintaining a quiet environment are all important requirements that must be met with any device, including an automatic one. It is mandatory to calibrate the

machine at regular intervals and to train personnel in the correct use of the device.

This study reconfirms earlier reports showing that systolic BP values are fairly well correlated with the weight and age of the patients,^{2,11} but the correlation is poor for diastolic and mean pressures. Although weight was slightly better correlated with systolic BPs than was age, we recommend that age be used to express normative values rather than weight for practical reasons. Similarly, although some people recommend that BP levels in growing children be related to height,⁶ we found that height was not better correlated to blood pressure levels than was age.

Some investigators recommend averaging two or three BP readings in children,^{6,21} but others do not.²² In children 11 to 17 years old, Hohn et al²² found no difference between the first BP readings and the average of three readings or that of the two subsequent readings. Using the auscultatory method in adult patients, the average of the triplicate measurements was found to be the same as a single measurement.²³

Obtaining three readings is not always possible in infants and children. Comparison of the first BP readings against the average of two latter readings and that of three readings reveals a certain pattern (Table 2). The first reading was not different from the average of multiple readings in infants younger than 1 year of age. After infancy, the first reading may be 1 to 4 mm Hg higher than the average of multiple readings. Apprehension associated with BP measurement may be responsible for the higher first reading seen in small children. Although the average of three readings may represent more basal and reproducible BP values,¹¹ in view of the relatively small clinical difference, we feel that one reading may be acceptable in daily practice as long as the above trend is taken into consideration in the interpretation of BP values.

This study also provides normative values for heart rate for this same group of children. The values have the advantage of being taken with minimal apprehension and, consequently, are likely to reflect the normal rate. The number of measurements made no difference in children younger than 3 years of age.

However, the first reading of the heart rate was 1 to 2 beats per minute lower than the average multiple-measurement values in children 3 years of age and older. The reason for this is not clear.

There are several advantages of the Dinamap Monitor over conventional or other noninvasive methods of BP measurement.^{12,13} Since it detects pressure oscillation, not sounds, the Dinamap Monitor can be used in neonates and small infants in whom Korotkoff sounds are usually too weak to give accurate readings. It can be used in a noisy environment or by a person with a hearing impairment. Observer-related variation and/or bias is completely eliminated; thus, there is no need for a long period of training personnel or a need to use a random zero device that is impractical in daily pediatric practice. A receptionist can easily be trained to use this device. The controversy over the choice between Korotkoff phase IV and phase V for diastolic pressure is not a problem. It also gives mean pressure and heart rate. An important drawback of this device is its relatively high cost for the average pediatrician. At the time this article was prepared, a Dinamap Monitor cost approximately \$3100.

The results of this study show that it is possible to obtain BP measurement in infants and small children using an automatic device. Currently, the NIH Task Force recommends routine BP determination by the auscultatory method in children 3 years of age and older.² It appears that routine BP determination should be practiced regardless of the age of patients when an oscillometric device is available. We found the Dinamap Monitor to be well accepted by most of our patient population. Three readings were possible in 87% of children younger than 3 years of age and in all children 3 years of age and older. This device was accepted by the patients 94% of the time for one reading in children younger than 3 years of age.

Our experience with oscillometric measurements of BP shows this to be more easily applicable in infants and small children than the conventional auscultatory method. Our normative data are generally in agreement with published values,² but show somewhat smaller variance. This may be because

our method precludes observer bias or variability, because a single consistent method and cuff size criterion were used, or because triplicate measurements were averaged. Finally, even with this method, problems and variables associated with indirect BP measurement still exist and should be controlled according to well-established guidelines.^{1,2,6}

This study was supported in part by a grant from the John Nuhn Research Foundation, Austin, Tex.

The authors are grateful to pediatricians and their staffs of the following offices and clinics in San Antonio, Tex, for their enthusiastic cooperation and support for this study: Northwest Pediatric Group, Northeast Pediatric Associates, Maxicare San Antonio Inc, Brook Army Medical Center, and Brady-Green Pediatric Clinics.

Dr Park and Ms Menard have no commercial or proprietary interest in the Dinamap Monitor or any financial interest (as consultant, reviewer, or evaluator) in the Dinamap Monitor.

Insulinlike Growth Factors in Patients With Active Nephrotic Syndrome

Eduardo H. Garin, MD; Maria B. Grant, MD; Janet H. Silverstein MD

• The serum concentrations of insulinlike growth factors 1 and 2 (IGF-1 and IGF-2) were measured by specific radioimmunoassays in 25 nephrotic patients. The serum concentration of IGF-1 in nephrotic patients (mean \pm SEM, 169 ± 17 ng/mL) was significantly lower than that observed in 20 control subjects matched for sex and age (338 ± 36 ng/mL). The IGF-2 serum concentration was significantly lower in nephrotic patients (343 ± 22 ng/mL) than in control subjects (898 ± 80 ng/mL). The IGF-1 and IGF-2 150-kd and 45-kd carrier protein complexes were found in the urine of nephrotic patients, whereas there was no binding of radiolabeled IGF-1 or IGF-2 to IGF carrier proteins in the urine of control subjects. The low serum IGF-1 and IGF-2 levels observed in nephrotic patients could be partially due to the increased urinary losses of the IGF carrier proteins.

(AJDC. 1989;143:865-867)

Insulinlike growth factors (IGFs) are polypeptide hormones that mediate growth hormone action on cartilage cell metabolic activity and skeletal growth.¹ They circulate in the plasma specifically bound to one or more carrier proteins.² Free IGF represents less than 1% of the total IGF.³ The circulating IGF carrier protein complexes presumably serve as a storage site for these hormones in the body.²

Growth failure was frequently seen in edematous nephrotic children prior to the introduction of steroid therapy,⁴ and continues to be a problem for the patient who currently fails to respond to this mode of therapy. Because nephrotic

syndrome is characterized by increased glomerular permeability to plasma proteins,⁵ and because the IGFs are mostly bound to the carrier proteins, the urinary loss of the carrier protein could result in decreased plasma levels of IGFs, thus contributing to growth failure in those patients with persistent nephrotic syndrome.

The purpose of this study was to measure serum IGF-1 and IGF-2 levels in patients with active nephrotic syndrome and to determine the presence of the carrier proteins in the urine of the nephrotic patients.

PATIENTS AND METHODS

Twenty-five patients with active nephrotic syndrome and 20 control subjects matched for age and sex were included in the study. Seventeen patients had minimal lesion nephrotic syndrome, 5 had focal segmental glomerulosclerosis, and 3 had mesangial proliferative glomerulonephritis. There were 19 boys and 6 girls. Their ages ranged from 3 to 18 years, with a median age of 10 years.

All patients had active nephrotic syndrome, defined as massive proteinuria (>50 mg/kg per day or 40 mg/m² per hour or $3+$ by Albustix [Miles, Elkhart, Ind]) associated with low serum albumin levels (<0.25 g/L). All patients had normal serum creatinine concentration for age and had not received glucocorticoid therapy for at least 1 month prior to the study.

Serum concentrations of IGF-1 and IGF-2 were measured by the radioimmunoassay technique of Zapf et al⁶ after the growth factors were separated from their binding proteins by acid chromatography. The IGF labeled with iodine 125 was prepared in the laboratory of one of us (M.B.G.). The specific radioactivity of the labeled peptides was approximately 100 Ci/g. The radioactive iodine content was between 0.25 and 0.5 atoms per molecule of IGF.

Acid chromatography was performed on G-50 Sephadex columns (1×10 cm) (Pharmacia, Piscataway, NJ) using 0.5 mol/L of acetic acid. The fractions, eluting at 50% to 80%

bed volume, were combined, refrozen, lyophilized, and neutralized with 2 mL of 0.1 mol/L of ammonium bicarbonate. This again was refrozen, lyophilized, and brought into solution with 0.05 mol/L of phosphosaline buffer, pH 7.4. Aliquots of this were used for the radioimmunoassay with all samples made in duplicate.

For serum, the final dilutions were 1:200 and 1:400 for IGF-1 and 1:400 and 1:800 for IGF-2. Cross-reactivity of IGF-2 in the IGF-1 assay was 1%, and cross-reactivity of IGF-1 in the IGF-2 assay was 10%. Values in this study were corrected for this cross-reactivity. Internal standards in each assay were used to minimize interassay variation. These internal standards consist of three chromatographed sera, one from an acromegalic subject and two from control subjects. The latter were similarly used for the IGF-2 assay. Each internal standard was assayed at four dilutions in duplicate. The interassay variations for the IGF-1 and IGF-2 radioimmunoassay were 14.8% and 11.3%, respectively, while the intra-assay variations were 2.3% and 2.5%, respectively.

The presence of the carrier proteins for IGF-1 and IGF-2 in the urine of seven patients (four with minimal lesion nephrotic syndrome and three with focal glomerulosclerosis) and three control subjects matched for age was assessed. Urine was collected from each subject during a 24-hour period. The urine pH was maintained at neutrality during the collection. The urine was frozen, lyophilized, and then resuspended in 10 mL of distilled water. The sample was then filtered using Whatman GF/D microfiber filters (Whatman, Clifton, NJ) to remove any particulate matter. A 0.1-mL aliquot of urine was then incubated with either 30 000 cpm of ¹²⁵I-IGF-1 or ¹²⁵I-IGF-2 (specific activity: 100 Ci/g, radioactive iodine content was 0.25 to 0.5 atoms per molecule of IGF) for 24 hours at 4°C.

The reaction mixture was then applied to a 1.5×70 -cm column of Sephacryl S-200 that had been equilibrated with 0.05 mol/L of sodium phosphate (pH 7.4), 0.15 mol/L of sodium chloride, and 0.02% sodium azide and calibrated with human IgG (molecular weight [MW] = 156 kd), human transferrin

(MW=88 kd), egg albumin (MW=45 kd), and chymotrypsin (MW=25 kd). The sample was then eluted with 0.05 mol/L of phosphate-buffered saline at 4°C with a linear flow rate of 16 mL/h. Fractions (1.6 mL) were collected and assessed for radioactivity. The binding proteins identified by this method were found to be specific for IGF-1 and IGF-2 in our previous studies.⁷

Serum albumin and creatinine levels were measured using a Technicon autoanalyzer II (Technicon, Atlanta, Ga). Urinary protein was determined using the sulfosalicylic-sodium sulfate test.⁸ Statistical analyses were performed using Student's *t* test for independent samples. Student's *t* tests were performed on the logarithms of the measured values of IGF-1 and IGF-2.

RESULTS

The serum concentration of IGF-1 in nephrotic patients (mean \pm SEM, 169 ± 17 ng/mL) was significantly lower than that observed in the control subjects matched for sex and age (338 ± 36 ng/mL, $P < .0001$). No significant differences were seen between the serum IGF-1 levels of patients with minimal lesion nephrotic syndrome (166 ± 24 ng/mL) and those of patients with other glomerulopathies (176 ± 30 ng/mL) (Table).

The mean IGF-2 serum concentration was significantly lower in nephrotic patients (343 ± 22 ng/mL) than control subjects (898 ± 80 ng/mL, $P < .001$). No statistically significant differences were found between IGF-2 serum levels of patients with minimal lesion nephrotic syndrome (338 ± 25 ng/mL) and patients with other glomerulopathies (356 ± 47 ng/mL).

The Sephacryl gel filtration of urine from seven nephrotic patients preincubated with ¹²⁵I-IGF-1 and ¹²⁵I-IGF-2 resulted in three peaks. The first peak had an apparent MW of 150 kd, the second peak had an MW of 45 kd, and the third peak represented excess unbound ¹²⁵I-IGF. All patients showed the same eluting pattern. A representative chromatogram is depicted in the Figure. There was no binding of radiolabeled IGF-1 and IGF-2 to IGF carrier proteins in the urine samples from the control subjects. Only unbound ¹²⁵I-IGF was detected on their chromatograms.

COMMENT

This study demonstrates that patients with active nephrotic syndrome

Insulinlike Growth Factor (IGF)1 and IGF-2 Serum Concentration in Nephrotic Patients		
	Mean \pm SEM	
	Nephrotic Patients (n=25)	Control Subjects (n=20)
IGF-1, ng/mL	$169 \pm 17^*$	338 ± 36
IGF-2, ng/mL	$343 \pm 22^\dagger$	898 ± 80

* $P < .0001$ compared with control subjects.

$^\dagger P < .001$ compared with control subjects.

The pattern of radioactivity eluting from a Sephacryl S-200 column is shown after incubation of insulinlike growth factors 1 and 2 (IGF-1 and IGF-2) labeled with iodine 125 with urine from nephrotic patients. The 150 kd represents the eluting peak for the 150-kd complex; the 45 kd indicates the eluting peak for the 45-kd complex. The third peak shows excess unbound ¹²⁵I-IGF-1 and ¹²⁵I-IGF-2.

have decreased serum levels of both IGF-1 and IGF-2 peptides. Furthermore, the decreased concentration was found regardless of the underlying pathologic features (minimal lesion nephrotic syndrome or other glomerulopathies). The low IGF-1 and IGF-2 levels could be due to decreased synthesis

of peptides, or increased urinary losses of the plasma carrier proteins, or both.

Insulinlike growth factor 1 is considered to be a sensitive marker of nutrition, particularly of dietary protein intake.⁹ Plasma levels of IGF-1 are known to be decreased in protein-energy malnutrition and after fasting.^{10,11} The nega-

tive nitrogen balance observed in patients with nephrotic syndrome may therefore explain the low IGF-1 serum levels found. However, periodic dietary recalls in our patients suggested adequate protein and energy intake. Moreover, though in negative nitrogen balance due to the massive proteinuria, nephrotic patients have increased hepatic protein synthesis.¹² Therefore, amino acids are available for the liver to synthesize albumin, IGFs, and other proteins, whereas protein wasting is seen in other organs, such as muscles. Thus, it is unlikely that nutritional factors alone can explain the decreased serum concentration of the IGFs.

Growth hormone regulates the hepatic production of the IGFs.¹³ The IGF-1 serum levels are far more growth hormone dependent than those of IGF-2. Children with nephrotic syndrome have normal basal and peak growth hormone levels to insulin provocation,¹⁴ suggesting that the decreased IGF-1 level is not due to inadequate growth hormone synthesis or release.

Insulinlike growth factor 1 and IGF-2 circulate in the plasma bound to specific carrier proteins.² Approximately 80% of the IGFs in normal plasma are carried as a part of a 150-kd MW complex that

appears to be under growth hormone control. The remainder of the IGFs are bound to a smaller complex with an estimated MW between 30 and 50 kd. The amount of this "45-kd" binding protein complex in plasma is less firmly linked to growth hormone than is the 150-kd form.

In this study, the 150-kd and the 45-kd carrier proteins were found in the urine of the nephrotic patients but not in control subjects whose urine did not have detectable amounts of these proteins. These increased urinary losses are due to the increase in glomerular permeability to plasma proteins, which is characteristic of patients with nephrotic syndrome.⁵ The 150-kd and 45-kd complexes were found in the urine of all seven patients with nephrotic syndrome, regardless of whether they were patients with minimal lesion nephrotic syndrome or other glomerulopathies.

Consistent with this finding, there were no significant differences between the serum levels of IGF-1 and IGF-2 in case patients with minimal lesion nephrotic syndrome and case patients with other glomerulopathies. A decrease in the plasma level of the active metabolite due to the urinary losses of

the active metabolite-carrier protein complexes has been described in case patients with nephrotic syndrome,¹⁵⁻¹⁸ in whom decreased plasma levels of vitamin D-binding globulin and transferrin have been reported.¹⁵⁻¹⁶ These carrier proteins have been found in the urine in large amounts, and the urinary losses have been associated with low plasma levels of ionized calcium and iron deficiency anemia.¹⁶⁻¹⁷

Growth is the result of complex interactions between nutrition, anabolic and catabolic factors, and the response of the target organs. Insulinlike growth factors are considered to be anabolic hormones. Their effectiveness is antagonized by IGF inhibitors. These appear to be proteins that are not measured by the IGFs' radioimmunoassay.¹⁸ Low serum levels of IGFs are found during conditions associated with growth disturbances. Thus, it is tempting to speculate that, in the patient with persistent nephrotic syndrome, poor growth could be mediated, at least in part, by a decrease in circulating IGFs due to increased IGFs' urinary losses.

We thank R. R. Humbel, MD, and R. Roesch, MD, Zurich, Switzerland, for providing the antibodies against IGF-1 and IGF-2, raised in rabbits.

CARNATION®

GOOD NATURE™

Iron Fortified Follow-Up Formula

For babies over six months of age
eating solid foods

When baby reaches the solid food stage, approximately 6 months of age, formula is no longer his sole source of nutrition. Yet, whole milk* doesn't contain all the necessary vitamins and the high-carbohydrate cereals, fruits, and vegetables he eats are low in certain nutrients. And, older babies require less energy from fat¹ and more from protein².

Carnation®

GOOD NATURE™ Follow-Up Formula provides the added nutrients for the older baby's optimal growth and development. And it contains

more protein and calcium than starter formula to support the increased metabolic demands of bone mineralization and muscle mass growth.

The ratio of unsaturated to saturated fatty acids in GOOD NATURE is 2:1. GOOD NATURE is higher in monounsaturated fatty acids yet contains 28% less fat than starter formula to satisfy the changing needs of the older baby.

GOOD NATURE also has a carbohydrate blend of 63% corn syrup solids and 37% lactose to help assure tolerance. It contains 12 mg iron per quart to help ensure a sufficient supply at an age when inborn stores are depleted. GOOD NATURE costs less than starter formula and also tastes, smells, and looks like the real food baby is learning to enjoy.

When baby is ready for solid food, Mom may ask you about GOOD NATURE Follow-Up Formula. You can reassure her that GOOD NATURE is nutritionally sound and makes good sense for her baby.

For more information about GOOD NATURE Follow-Up Formula, please write to:
Carnation Nutritional Products,
5045 Wilshire Blvd., Los Angeles, CA 90036.

Carnation®

*Setting the stage
for better development™*

GOOD NATURE Follow-Up Formula...
now available to consumers in
32-fl-oz ready-to-feed fresh packs
and 12-oz easy-to-mix powder canisters.

Ryan's running, thanks to a miracle!

Ten-year-old Ryan Shewell contracted pneumococcus septicemia at age 9. Upon admission to Children's Hospital and Medical Center in Seattle, physicians discovered that Ryan was born without a spleen. Debridement surgeries saved Ryan's life... but both legs were amputated below the knee. Today, with prostheses and physical therapy, Ryan is back to playing soccer with his friends. His family gives thanks to Ryan's unfailing spirit... and to the hospital, funded in part by Children's Miracle Network.

The Children's Miracle Network Telethon is the one national fund-raising appeal specifically for hospitals for children throughout the United States and Canada. In 1988, the telethon raised over \$60 million, making it the largest telethon.

One hundred percent of the money raised goes directly to individual hospitals for children... so that miracles like Ryan's can happen for the 5,000,000 children treated each year.

A DIVISION OF ABBOTT LABORATORIES, USA

RICHARD W. GAST
PRESIDENT

... on the consumer promotion of infant formula.

There is a development that undermines your control over the infant's diet and health, and that undermines breastfeeding—the advertisement of formulas directly to the mother through TV, magazines and mail.

On June 1, the President of the American Academy of Pediatrics sent a letter to all Fellows of the Academy reaffirming its stance against consumer advertising, and expressing concern that other formula companies might follow Nestlé/Carnation.

This concern was justified. On June 15, it was announced at a press conference that Mead Johnson/Bristol-Myers will be producing an infant formula to be sold and marketed under the Gerber label. Part of the program is a multimillion-dollar budget for advertising the formula directly to mothers via TV and print.

Speaking at the press conference, Gerber Products Division President Robert L. Johnston, Jr., said that Gerber was entering the market because it had, "identified significant changes in usage that convinced us the timing was right. ..."

"First," he said, "there is a rapid decline in breast-feeding after mothers leave the hospital." And, "... parent decision regarding baby formula brand selection has grown. ..."

The irony is inescapable and appalling. In other words, because breastfeeding is declining, more infant formulas should be promoted to the mother. In other words, because some mothers are making feeding decisions on their own, even more mothers should follow suit.

When Nestlé/Carnation entered the marketplace and, again, when Mead Johnson/Bristol-Myers joined with Gerber, we reexamined the Ross philosophy of promoting SIMILAC® Infant Formulas. The result of our deliberations was an even deeper resolve to support the doctor/patient relationship.

Our philosophy remains unchanged. Ross Laboratories has no plans to resort to direct consumer advertising for SIMILAC and our other infant formula products.

We will continue as an ally of health care professionals by supporting your prerogative to prescribe and recommend products as training and experience dictate.

We stand behind you.

Richard W. Gast

884 INSTRUCTIONS FOR AUTHORS

AJDC, American Journal of Diseases of Children (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the American Journal of Diseases of Children are as follows: \$48 for one year, \$81 for two years in the United States and US Possessions; all other countries, one year, \$58; two years, \$101 for surface delivery. (For expedited air delivery to most countries, add \$15 surcharge for one year subscription, \$30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. **Special rates for residents and medical students in the United States and US Possessions are available.** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312) 280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes for AJDC, American Journal of Diseases of Children. Attention: Subscription Department, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

ADVERTISING OFFICES: Eastern: 600 Third Ave, Suite 3700, New York, NY 10016 (Manager: Robert C. Corcoran [212-867-6640]; Representative: Phillip B. Altamore); Midwest/Farwest: 535 N Dearborn St, Chicago, IL 60610 (Manager: Thomas J. Carroll [312-280-7182]; Representative: John P. Cahill, Midwest/Farwest)

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

Growing up on a steady theophylline is an open-and-shut case

Sprinkled

Intact

Changing your patients from sprinkled to solid theophylline administration shouldn't mean changing their serum levels as well. With Slo-bid, you won't change a thing when your younger asthma patients are ready to switch to intact administration.

Slo-bid maintains steady theophylline levels when switching from sprinkled to solid administration¹

Switching from Slo-bid sprinkled to Slo-bid intact causes virtually no change in serum levels. Since the release system doesn't change, theophylline performance with both forms is identical. There's no need to restabilize your patients when they switch to taking capsules. In addition, capsules are the dosage form more patients prefer to take.²

Keep your patients' theophylline levels steady. Start and stay with Slo-bid. It's the perfect theophylline system for asthma patients to grow up with.

Slo-bid™

(theophylline, anhydrous)

50 mg, 75 mg, 100 mg, 125 mg, 200 mg, and 300 mg

Gyrocaps®

Timed-Release Capsules

BRIEF SUMMARY

DESCRIPTION: Slo-bid™ Gyrocaps® contain 50 mg, 75 mg, 100 mg, 125 mg, 200 mg, or 300 mg theophylline, anhydrous in the form of long-acting beads within a dye-free hard gelatin capsule and are intended for oral administration. Slo-bid Gyrocaps can be administered with a 12-hour dosing interval for a majority of patients and a 24-hour dosing interval for selected patients (see DOSAGE AND ADMINISTRATION section in full prescribing information for description of appropriate patient population).

INDICATIONS AND USAGE: For relief and/or prevention of symptoms from asthma and reversible bronchospasm associated with chronic bronchitis and emphysema.

CONTRAINDICATIONS: Slo-bid is contraindicated in individuals who have shown hypersensitivity to any of the components of this product. It is also contraindicated in patients with active peptic ulcer disease and in individuals with underlying seizure disorders (unless receiving appropriate anticonvulsant medication).

WARNINGS: Serum levels above 20 µg/mL are rarely found after appropriate administration of the recommended doses. However, in individuals in whom theophylline plasma clearance is reduced for any reason, even conventional doses may result in increased serum levels and potential toxicity. Reduced theophylline clearance has been documented in the following readily identifiable groups: 1) patients with impaired renal or liver function; 2) patients over 55 years of age, particularly males and those with chronic lung disease; 3) those with cardiac failure from any cause; 4) patients with sustained high fever; 5) neonates and infants under 1 year of age; and 6) those patients taking certain drugs (see PRECAUTIONS, Drug Interactions). Frequently, such patients have markedly prolonged theophylline serum levels following discontinuation of the drug.

Reduction of dosage and laboratory monitoring is especially appropriate in the above individuals.

Serious side effects such as ventricular arrhythmias, convulsions, or even death may appear as the first sign of toxicity without any previous warning. Less serious signs of theophylline toxicity (i.e., nausea and restlessness) may occur frequently when initiating therapy but are usually transient; when such signs are persistent during maintenance therapy, they are often associated with serum concentrations above 20 µg/mL. Stated differently, *serious toxicity is not reliably preceded by less severe side effects.* A serum concentration measurement is the only reliable method of identifying a potential for life-threatening toxicity.

Many patients who require theophylline exhibit tachycardia due to their underlying disease process, so the cause/effect relationship to elevated serum theophylline concentrations may not be appreciated.

Theophylline products may cause dysrhythmia and/or worsen preexisting arrhythmias and any significant change in rate and/or rhythm warrants monitoring and further investigation.

Studies in laboratory animals (minipigs, rodents, and dogs) recorded the occurrence of cardiac arrhythmias and sudden death (with histologic evidence of myocardial necrosis) when beta agonists and methylxanthines were administered concurrently. The significance of these findings when applied to humans is currently unknown.

PRECAUTIONS: General: On the average, theophylline half-life is shorter in cigarette and marijuana smokers than in nonsmokers, but smokers can have half-lives as long as nonsmokers. Theophylline should not be administered concurrently with other xanthine preparations. Use with caution in patients with hypoxemia, hypertension or with a history of peptic ulcer. Theophylline may occasionally act as a local irritant to the GI tract, although GI symptoms are more commonly centrally mediated and associated with serum drug concentrations over 20 µg/mL.

Information for Patients:

The physician should reinforce the importance of taking only the prescribed dose at the prescribed time intervals. The patient should alert the physician if symptoms occur repeatedly, especially near the end of a dosing interval. When prescribing administration by the sprinkle method, details of the proper technique should be explained to the patient.

Laboratory Test: Serum levels should be monitored periodically to determine the theophylline levels associated with observed clinical response and to identify the potential for toxicity. For such measurements, the serum sample should be obtained at the time of peak concentration, approximately 5-9 hours after the morning dose. It is important that the patient has not missed or taken additional doses during the previous 48 hours and that dosing intervals have been reasonably equally spaced.

DOSE ADJUSTMENT BASED ON SERUM THEOPHYLLINE MEASUREMENTS WHEN THESE INSTRUCTIONS HAVE NOT BEEN FOLLOWED MAY RESULT IN RECOMMENDATIONS THAT PRESENT RISK OF TOXICITY TO THE PATIENT.

Drug Interactions:

Drug-Drug: Toxic synergism with ephedrine has been documented and may occur with some other sympathomimetic bronchodilators. In addition, the following drug interactions have been demonstrated:

Theophylline with:	Increased serum theophylline levels
Allopurinol (high dose)	Increased serum theophylline levels
Cimetidine	Increased serum theophylline levels
Erythromycin, Troleandomycin	Increased renal excretion of lithium
Lithium carbonate	Increased serum theophylline levels
Oral contraceptives	Decreased theophylline and phenytoin serum levels
Phenytoin	Decreased serum theophylline levels
Rifampin	

Drug-Food: Taking Slo-bid immediately after a high-fat content meal such as 8 ounces whole milk, 2 fried eggs, 2 strips bacon, one bran muffin with butter, 2 ounces hash brown potatoes (about 789 calories, including approximately 49 gm of fat) may result in a decrease in the rate of absorption, but with no significant difference in the extent of absorption (see CLINICAL PHARMACOLOGY, Pharmacokinetics). The influence of the type and amount of other foods, as well as the time interval between drug and food, has not been studied.

Drug/Laboratory Test Interactions: Currently available analytic methods, including high-pressure liquid chromatography and immunoassay techniques, for measuring serum theophylline levels are specific. Metabolites and other drugs generally do not affect the results. Other new analytic methods are also now in use. The physician should be aware of the laboratory method used and whether other drugs will interfere with the assay for theophylline.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies have not been performed with theophylline.

Chromosome-breaking activity was detected in human cell cultures at concentrations of theophylline up to 50 times the therapeutic serum concentrations in humans. Theophylline was not mutagenic in the dominant lethal assay in male mice given theophylline intraperitoneally in doses up to 30 times the maximum daily human oral dose.

Studies to determine the effect on fertility have not been performed with theophylline.

Pregnancy: Pregnancy Category C—Animal reproduction studies have not been conducted with theophylline. It is also not known whether theophylline can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Theophylline should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Theophylline is distributed into breast milk and may cause irritability or other signs of toxicity in nursing infants. Because of the potential for serious adverse reactions in nursing infants from theophylline, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use:

Safety and effectiveness of Slo-bid Gyrocaps administered:

1. Every 24 hours in children under 12 years of age, have not been established.
2. Every 12 hours in children under 6 years of age, have not been established.

ADVERSE REACTIONS: The following adverse reactions have been observed, but there has not been enough systematic collection of data to support an estimate of their frequency. The most consistent adverse reactions are usually due to overdosage.

Gastrointestinal: nausea, vomiting, epigastric pain, hematemesis, diarrhea.

Central Nervous System: headaches, irritability, restlessness, insomnia, reflex hyperexcitability, muscle twitching, clonic and tonic generalized convulsions.

Cardiovascular: palpitation, tachycardia, extrasystoles, flushing, hypotension, circulatory failure, ventricular arrhythmias.

Respiratory: tachypnea.

Renal: potentiation of diuretics.

Other: alopecia, hyperglycemia, inappropriate ADH syndrome, rash.

CAUTION: Federal (U.S.A.) law prohibits dispensing without prescription. Keep this and all medications out of the reach of children.

HOW SUPPLIED: Slo-bid Gyrocaps are identified as follows:

- 50 mg—Clear (cap) and opaque white (body) capsule with 50 printed in red
- 75 mg—Opaque white (cap) and clear (body) capsule with 75 printed in red
- 100 mg—Clear capsule with 100 printed in red
- 125 mg—Opaque white (cap) and opaque white (body) capsule with 125 printed in red
- 200 mg—Opaque white (cap) and clear (body) capsule with 200 printed in red
- 300 mg—Opaque white capsule with 300 printed in red

Slo-bid Gyrocaps 50 mg are available in bottles of 100 (NDC 0075-0057-00), bottles of 1000 (NDC 0075-0057-99) and in unit dose 10 x 10 (NDC 0075-0057-62). Slo-bid Gyrocaps 75 mg are available in bottles of 100 (NDC 0075-1075-00), bottles of 1000 (NDC 0075-1075-99) and in unit dose 10 x 10 (NDC 0075-0057-62). Slo-bid Gyrocaps 100 mg are available in bottles of 100 (NDC 0075-0100-00), bottles of 1000 (NDC 0075-0100-99) and in unit dose 10 x 10 (NDC 0075-0100-62). Slo-bid Gyrocaps 125 mg are available in bottles of 100 (NDC 0075-1125-00), bottles of 1000 (NDC 0075-1125-99) and in unit dose 10 x 10 (NDC 0075-1125-62). Slo-bid Gyrocaps 200 mg are available in bottles of 100 (NDC 0075-0200-00), bottles of 1000 (NDC 0075-0200-99) and in unit dose 10 x 10 (NDC 0075-0200-62). Slo-bid Gyrocaps 300 mg are available in bottles of 100 (NDC 0075-0300-00), bottles of 1000 (NDC 0075-0300-99) and in unit dose 10 x 10 (NDC 0075-0300-62), and are manufactured by:

The Pediatric Forum

This department of AJDC is reserved for comment, criticism, observation, and discussion of "issues of current concern and importance for children's health." The Editor encourages our readers to express themselves on a variety of topics and issues. Further, we encourage the submission of unique and brief clinical and scientific observations that do not fulfill the criteria for original articles.

Campylobacter pylori Gastritis and Peptic Ulcer in Children

Sir:—We read with great interest the article by Kilbridge et al¹ in the December 1988 issue of *AJDC* on *Campylobacter pylori* (CP)-associated gastritis and peptic ulcer disease in children, which are becoming growing problems in pediatric gastroenterology. In fact, according to some authors CP is present in antral biopsies of up to 32%^{2,3} of children with recurrent abdominal pain severe enough to require gastroscopy. Even if the prevalence of CP infection is known to increase with age and, therefore, it is expected to be lower in the pediatric population, in children with primary gastritis the percentage of CP infection is as high as 60% to 80%^{4,5} and quite similar to the rate found in adults.

In a retrospective study we carried out on all gastroscopies performed in our center from 1983 to 1987, only 58 patients (8.6%) with primary gastritis were found, but in 70.7% of them CP was identified when the histological slides were reviewed. We feel that this figure, like the 55% reported by Kilbridge et al, underestimates the real prevalence of CP infection. In fact, we used to take biopsy specimens only from those gastric antra showing some changes at endoscopy, but we are now aware, as Kilbridge et al pointed out, that CP can colonize a normal-appearing antrum. The low figures reported could be due to the fact that their study was retrospective. We would like to emphasize the high prevalence of the CP infection in children that, in a prospective study we are presently conducting, is reaching more than 90% in children with primary gastritis or peptic ulcer disease.

Two points in the article by Kilbridge et al are of particular interest:

1. There was a predominance of chronic infiltrate antral CP gastritis in children, with less diffuse acute inflammatory component than in

adults. Their hypothesis that this represents an earlier phase of infection is attractive but does not seem to be confirmed by some of our observations.⁶ In fact, we too observed a higher prevalence of chronic gastritis in children with CP infection (26 cases vs 16 with acute inflammatory infiltration), but after amoxicillin treatment, which cleared the infection in 85% of the children and healed the gastritis in 67%, we observed a recurrence in 73% of the patients 3 months after stopping the treatment. We think that these recurrences could be considered as an early phase of infection since 3 months earlier gastritis was not present. Sixty percent of these children who suffered a relapse showed an acute gastritis.

2. There was a high relapse rate (80%) of duodenal ulcer in patients with CP gastritis. This finding may indicate that CP presence in antral mucosa portends an unfavorable prognosis. In a long-term follow-up study of children with peptic ulcer treated with ranitidine, we observed a relapse rate of 47% of 31 patients; CP was present in 85% of children who had a relapse but only in 29% of those who did not.⁷

Sir:—Although a rapidly expanding body of literature provides much information concerning the prevalence and the significance of CP in adults,¹ there is little information as to whether the association of this organism with histologic gastritis represents in childhood a causal relationship or merely an association. After reading the article by Kilbridge et al, we were stimulated to report in brief our preliminary data to address this question.

Recently we initiated a prospective study in which we attempted to identify CP in antral biopsies obtained from children undergoing upper gastrointestinal tract endoscopy for chronic abdominal pain, hematemesis, vomiting, and unexplained iron-deficiency anemia. To date, complete evaluation has been obtained on 24 children.

In 11 of the 24 antral biopsies, the light microscopy showed evidence of chronic gastritis, which was characterized by a diffuse inflammatory cell infiltration of the lamina propria consisting of plasma cells and lymphocytes. *Campylobacter pylori* was detected by means of histological stains and culture in 10 of the 11 children with chronic gastritis. None of the 13 patients with histologically normal antral mucosa had CP demonstrated on their antral biopsy specimens. The presence of the bacterium was associated with mild as well as moderate to severe inflammatory changes of the antral mucosa. The association of CP even with mild gastritis provides further support that this organism represents an inciting factor for antral gastritis in children.

Surprisingly, the antral biopsies did not indicate the presence of CP as a marker of "active" histological gastritis. In fact, the histological appearances were never associated with signs of activity.² Kilbridge et al suggested that the "inactive" chronic inflammation observed in the younger subjects in their study may represent an earlier phase of infection.

In our study, patients with CP-associated gastritis were older (mean age, 9.8 years) than those who did not present this condition (mean age, 6.7 years). As previously described in adults,³ it is possible that "active" chronic gastritis due to CP may be limited also in children to a patchy distribution and may not be present at the site of detection of the organism. Finally, six patients who received a 4-week course of monotherapy with amoxicillin trihydrate (50 mg/kg per day in three divided doses) exhibited eradication of the organism, which was associated with a marked improvement or complete resolution of the inflammatory changes of the gastric mucosa. After 6 to 18 months of cessation of therapy, the patients continue to be asymptomatic.

As Kilbridge et al point out, additional prospective long-term follow-up studies may help to clarify further the role of CP in the pathogenesis of antral gastritis in children.

In Reply.—Chiesa et al and Oderda et al agree with us regarding the high prevalence of CP infection and its relationship to antral gastritis and

duodenal ulcer.

The highly effective results of antimicrobial therapy reported by Chiesa et al are interesting. To date, we have been unsuccessful in eradicating CP with amoxicillin monotherapy. Our results are in agreement with recently reported adult studies by Rauws et al,¹ as well as pediatric studies by De Giacomo et al.² The latter group had no success in eradicating CP or improving the underlying gastritis in their pediatric patients. The experience cited above by Oderda et al also indicates failure to achieve permanent eradication of the organism with ampicillin. We look forward to the publication of the study done by Chiesa et al. Perhaps we may be able to determine why we and others have not been successful in our efforts to eradicate CP. We agree with Dr Oderda and his colleagues that children with CP gastritis and duodenal ulcer are very likely to suffer ulcer relapse if they are treated with standard H₂ antagonist therapy alone and the CP infection is not eradicated.

Both Chiesa et al and Oderda et al have additional observations regarding the relative roles of acute and chronic inflammation in CP gastritis. In pathologic parlance, the term *active gastritis* as used by Chiesa et al means acute inflammatory cells are present in the tissue. They did not observe active gastritis in any of their CP infections; all the gastritis they observed was histologically chronic inflammation. Their experience again differs from ours and from the other published series of CP gastritis in children,^{3,6} where both chronic and acute inflammation are described. Oderda and colleagues also observed, as we did, that both chronic and acute inflammation are present, with chronic gastritis predominating. Oderda et al suspect that acute inflammation is present from the start of CP infection in some patients, since they observed acute gastritis within 3 months of reinfection with CP.

European gastroenterologists, such as Chiesa and Oderda, appear to be more interested than their American colleagues in CP and more convinced of its pathogenic role in upper gastrointestinal tract disease.

Hyperuricosuria and Microhematuria in Childhood

Sir.—Microhematuria is a common finding in pediatrics that frequently requires multiple diagnostic procedures¹ to determine its cause, which in many cases remains uncertain.

Among the multiple possible causes, Stapleton et al² pointed out the role hypercalciuria would play in the pathogenesis of certain types of microhematuria. We have found an association between hyperuricosuria and microhematuria in five otherwise-healthy children. We think that a pathogenic mechanism is operative that is similar to the one reported by Stapleton et al² for microhematuria secondary to hypercalciuria. The small number of patients tested only suggests this possibility and the pilot experience reported herein will require further investigation.

Patients and Methods.—Five children (2 boys and 3 girls), whose ages ranged from 4 to 9 years, were selected from a total of 139 patients with microhematuria because they presented abnormally high levels of uricosuria with no other underlying cause.

In one of the children the onset of the disorder was accompanied by gross hematuria and colic pain (with no calculi expulsion) and microhematuria that persisted after this episode. In the remainder of the patients the condition was asymptomatic and the persistence of microhematuria was assessed by examination of at least five consecutive urine specimens.

Renal function (serum urea and creatinine levels and creatinine clearance) was normal in all patients. Results of coagulation studies, 24-hour calciuria measurement, intravenous pyelography, and cystourethrography were all normal. Diseases causing hypouricemia were eliminated and the possibility of exposure to drugs or heavy metals was also considered.

Microhematuria was defined by the presence of more than 15 red blood cells per high-power field in fresh urinary sediment

Table 1.—Analytical Findings					
	Patient No.

Follow-up, mo	6	...	22	...

*Plus and minus signs are dipstick readings.

(counted in a Neubauer chamber) in at least five consecutive voidings.

The measurement of blood and urinary uric acid levels was done by the uricase enzymatic method.⁸

Results. — Increased uricosuria; measured in milligrams per 1.73 m^2 per day, and fractional excretion of uric acid higher than 20% were noted in all of our patients. Results of the examination of the urinary sediment in patients 1, 2, and 3 by phase-contrast microscopy⁴ were consistent with hematuria of nonglomerular origin.

Clinical and analytical data collected at the time of diagnosis are shown in Tables 1 and 2.

Two of the children (patients 2 and 3) with microhematuria and a slight elevation of fractional excretion of uric acid were maintained on a moderately restricted purine diet. This lowered the uricosuria to its normal range, and microhematuria disappeared from at least five repeated samples obtained within a 1-week interval.

The other three patients did not follow the diet adequately, hyperuricosuria persisted, and microhematuria did not resolve.

Comment. — Hematuria defined as more than 15 red blood cells per high-power field (microscopic or mac-

roscopic) is a frequent finding in childhood. Its prevalence has been estimated at 0.4%⁹ and it is a common cause of pediatric ambulatory visits (1.3 per 1000 patients).⁶

Microhematuria of the nonglomerular type has been associated with hypercalciuria that is possibly due to microscopic calculi originating in the tubular epithelium.² This hematuria resolves when calciuria returned to normal levels after adequate treatment.

A normal uricosuria value in childhood has already been defined (measured in milligrams per 1.73 m^2 per day) as a more accurate criterion that seems to increase proportionately with age variations and in relation to weight and height. For normal Spanish children the median (SD) value for uric acid fractional excretion is $643.66 (\pm 190) \text{ mg per } 1.73 \text{ m}^2 \text{ per day}$.⁷

We have found increased levels of uricosuria in five patients, accompanied by persistent microhematuria (and an episode of macroscopic hematuria in one of them), but with no evidence of urolithiasis in any of the cases, at the time of diagnosis and during follow-up. Other studied measures were all normal.

Erythrocyte structures, in the three cases in which they were observed,

were of the nonglomerular type that is seen in hypercalciuria, suggesting a similar pathogenic mechanism.

The fact that uricosuria decreased in two of our patients after institution of a purine-restricted diet, along with the disappearance of microhematuria, seems to confirm this hypothesis.

Hyperuricosuria seems to be another possible cause of microhematuria in childhood (although it has not yet been reported in the literature), as suggested by the results of our study. We advise the measurement of uricosuria in those children who have persistent microhematuria and normal clinical and analytical data.

The long-term risk for the development of urolithiasis in these patients with hyperuricosuria and hematuria remains unknown, requiring a more extensive follow-up. The detection of high values of uricosuria suggests that assay of renal tubular handling of uric acid is necessary in these patients.

Updating Immunization Status at Discharge

Sir. — Several benefits of a strategy to immunize children at the time of discharge from a community hospital were suggested recently.¹ We assessed the costs and feasibility of implementing this program in our hospital over a 4-week period.

Age Group and Health Insurance Status of All Children Admitted to the Hospital and Those Immunized at Discharge

Age Range, y	All Patients Admitted to Hospital			Patients Immunized at Discharge		
	No. of Patients	% of Total Patients	Indigent Patients, %	No. of Patients	% of Age Group	Indigent Patients, %
0-2	53	68	38	8	15	50
2-4	13	17	31	2	15	50
4-6	7	9	29	0
6-8	2	3	50	1	50	100
>8	3	4	67	0
Total	78	...	37	11	...	55

Materials and Methods.—The study was conducted at the Women's and Children's Hospital of the University of South Alabama Medical Center in Mobile during the month of November 1988. Our facility is a regional tertiary care center. Overall, 42% of the medical expenses for admissions to the pediatric floor are covered by private insurance carriers and 20% are covered by Medicaid. Thirty-eight percent of the patients are indigent.

The immunization status of all children admitted to the general pediatric service was assessed. The residents were asked to verify the information by asking the parents to bring in immunization records or by making telephone calls to previous health care providers. The dates and form of verification were recorded on a separate sheet for this prospective study. Each patient for whom the immunization status was not up to date according to the American Academy of Pediatrics recommendations² was considered eligible for immunization at discharge.

Live vaccines were withheld from children with suspected or documented viral illness to avoid interference. Oral polio vaccine was supplanted by inactivated poliovirus vaccine to avoid the contraindication of diarrhea and the remote risks to other patients in the event a patient had to be readmitted. Informed consent was required, and small children received prophylactic acetaminophen.

Results.—A total of 13 patients (17% of all hospitalized study patients) did not have up-to-date immunizations. Immunizations were given to 11 of the patients; 2 patients were not immunized. One of these patients was a 2-month-old infant admitted for "rule-out sepsis," and immunization-induced fever could have prompted another workup and admission. Immunization after discharge was recommended in the other patient because the experimental policy would have meant an undue delay in discharge.

The number of patients, their respective age groups, and their medical

insurance status are listed in the Table. A total of nine doses of diphtheria and tetanus toxoids and pertussis vaccine, eight doses of inactivated poliovirus vaccine, five doses of *Haemophilus influenzae* type b diphtheria conjugate, and two doses of measles-mumps-rubella vaccine were given. The total cost of the vaccines was \$312, of which \$158 would have been covered by insurance (all Medicaid patients in our survey). A higher proportion of indigent patients (55%) were found in the group needing immunization compared with all children admitted to the hospital (37%). None of the children immunized had an identifiable primary care physician.

Comment.—Although our study was limited to a few patients in a 1-month period only, it showed that in our setting about 14% of patients would benefit from a discharge immunization policy. None of the patients had any complications from the immunizations, nor did the immunization result in further telephone calls or visits to the emergency department. Results from our preliminary study suggest that such immunization programs are feasible and safe and may provide an important function in hospitals serving indigent patients. Another potential benefit from such a program might be from teaching residents on a "learn as you do" basis about this important aspect of preventive pediatrics.

Prevention of Accidental Extubations in Newborns

Sir.—We read with interest the article by Brown¹ that appeared in the November 1988 issue of *AJDC* concerning accidental extubations in newborns.

We have used a variation of the pinning method for endotracheal tube stabilization at our nursery for the past 4 years. This method is illustrated in the Figure. Our method is used exclusively in orally intubated newborns. The newborn's face is prepped with a tincture of benzoin, and elastic tape (Elastikon, Johnson and Johnson, New Brunswick, NJ) is used as illustrated. A 2.5-cm safety pin (presterilized) is carefully placed to minimize mechanical compromise of the endotracheal tube lumen. Shiley (Shiley Inc, Irvine, Calif) uncuffed pediatric oral/nasal Murphy endotracheal tubes are primarily used. It does take an initial orientation to become familiar with the technique, but once learned, respiratory therapists and nurses have reported minimal morbidity. We have found no problems with suctioning past the pin. In even 2.5-mm (inside diameter) tubes a 6.0F catheter can be inserted easily if care is taken to secure the pin properly. We have seen no incidents of downward migration of the endotracheal tube, ie, accidental displacement of the tube to the carina or into the right main-stem bronchus.

Using Dr Brown's lead, we retrospectively reviewed 37 patients undergoing ventilation in our neonatal intensive care unit. We initially looked at 22 patients selected consecutively over the last 2 months and found no accidental extubations over a period of 94 intubation days. We then selected an additional 15 patients at random over the last 2 years (September 1986 to September 1988). Of a total of 405 intubation days there were 12 recorded accidental extubations or 3.0 extubations per 100 intubation days. Of interest was that only 4 (10.8%) of 37 patients accounted for all of the extubations, and 2 patients (163 intubation days) accounted for 9 extubations. Consistent with Dr Brown's findings, both were extremely low-birth-weight infants. All of their extubations occurred after the first

A

B

C

D

E

F

G

H

Technique of securing the oral endotracheal tube.

month of life. If we looked only at the first month of life, we found only 3 accidental extubations of 298 intubation days or 1.0 extubation per 100 intubation days.

During our residency and fellowship training we have been involved with neonatal services at five separate university centers. Anecdotally, we have been uniformly impressed that this method in comparison with several variations on a taping method appeared superior.

We reviewed our numbers to bring attention to a particular technique of securing endotracheal tubes in newborns, and our experience with this technique as used in a community-based neonatal intensive care unit setting.

The method described in Brown's article appears quite effective. It would be interesting to see a prospective comparison of these two methods.

Simultaneous Transient Hyperphosphatasemia in a Set of Twins

Sir.—The diagnostic features of benign transient hyperphosphatasemia are (1) patient age of less than 5 years; (2) variable, usually unrelated symptoms; (3) no physical evidence for bone or liver disease; (4) no other biochemical or laboratory evidence for bone or liver disease (including normal isoenzymes, if test is done); and (5) a return to normal serum alkaline phosphatase level within 4 months with no sequelae.¹ The cause is unknown but proposed mechanisms include malnutrition, drug induction, viral infection, and transient impeded clearance of serum alkaline phosphatase.¹ The two patients described herein are, to our knowledge, the first set of twins who developed the syndrome simultaneously.

Patients and Methods.—These 11-month-old white male twins were well until an age of 9 months, when they developed severe diarrhea. Stool cultures from both were positive for *Salmonella*. No antibiotics were given. They continued to have frequent loose stools over the next 2 months, despite outpatient

trials of taking casein hydrolysate formula (Pregestimil), a liquid containing kaolin, pectin, hyosyamine sulfate, atropine sulfate, and scopolamine hydrobromide (Donnagel), and *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* (Lactinex), and trying elimination diets. Irritability, diarrhea, poor weight gain, and parental anxiety prompted workup.

On physical examination, both twins appeared alert, happy, and well hydrated. Both were at the 10th percentiles for height, weight, and head circumference. The only abnormalities noted were mild rhinorrhea and otitis media in both patients. No abnormal liver or bone findings were noted.

Results.—Both patients had the following tests done, with each having negative or normal results: complete blood cell count; glucose, urea nitrogen, creatinine, sodium, potassium, chloride, uric acid, calcium, cholesterol, creatine phosphokinase, aspartate aminotransferase, alanine aminotransferase, γ -glutamyltransferase, bilirubin, lactate dehydrogenase, total protein, albumin, IgG, IgA, IgM, carbon dioxide, serum pH, folate, carotene, phosphorus, and 1-hour blood xylose levels; stool tests for rotavirus, bacterial culture, parasites, pH, blood, and clintest; and a sweat test. Twin B also had a normal value for his IgE level, and a qualitative stool test for trypsin produced a normal result.

Twin A's initial alkaline phosphatase level was 2885 U/L (Table). Twin B's initial alkaline phosphatase level drawn at the same time was 896 U/L. Four weeks later, twin A's level was 303 U/L and twin B's level was 355 U/L. Both patients had normal levels 8 weeks later.

Both twins were given normal diets for their age. The mother was instructed to decrease their water and juice intake and to use whole milk to satisfy thirst. The otitis was treated with cefaclor. The diarrhea resolved and weight gain was documented. The parents reported no further episodes of diarrhea.

Comment.—Twin B's initial alkaline phosphatase value was lower than twin A's and probably represented our documenting the elevation on its way back to normal levels. It seems clear to us that their syndrome occurred simultaneously. The cause for transient, benign hyperphosphatasemia remains unknown. Our recent review¹ and letter² argued against the leaking of enzymes from severe liver and/or bone damage as a cause, while postulating that impeded clearance of the enzyme might be more plausible. The results reported herein

Alkaline Phosphatase Levels*			
	Alkaline phosphatase, U/L		
	Initial	After 4 wk	After 8 wk
Twin A	2885	303	403
Twin B	896	355	433

*Normal values in our laboratory in infants under 12 months of age are 170 to 450 U/L.

suggest that a genetic predisposition for impeded clearance of alkaline phosphatase may be triggered by an exogenous insult, such as a viral infection, acute nutritional deficiencies, or drugs. This, of course, does not explain the transient nature of the syndrome nor does it explain why 14 of 68 patients described were normal controls without evidence of insults of any kind (unless insults were so trivial as to be overlooked by the clinicians).¹ The syndrome continues to be an enigma, but careful clinical and laboratory observations may shed some light in the future.

Very-Low-Birth-Weight Infants

Sir.—In the January 1989 issue of *AJDC*, Georgieff et al¹ report on more aggressive early neonatal nutritional management, changes in cardiopulmonary management, and a lower incidence of chronic disease in 1986 compared with 1982. This has promoted earlier onset of, and a more rapid rate of, postnatal growth that extends to the first year of follow-up. The authors compared 37 of 82 very-low-birth-weight infants born in 1982 with 29 of 46 infants born in 1986, representing follow-up rates of 57% and 64%, respectively.

However, only 32 of the infants born in 1982 and 18 of those born in 1986 were followed up until 2 years of age. Thus, 32 (39%) of 82 infants and 18 (39%) of 46 infants received follow-up until 1 year of age. The authors compared the neonatal data of the 47

infants born in 1982 with those of the 29 infants born in 1986 and came to the conclusion that a more aggressive early nutritional regimen, changes in cardiorespiratory management, and a lower incidence of severe medical complications affected later growth of the infants.

I have serious concerns about reporting data on the outcome of about one third of a population when two thirds of the population have been unavailable for follow-up. I also have serious concerns about coming to conclusions over changes in neonatal care when only 57% and 64% of the neonatal patients' data have been compared. To evaluate whether changes in neonatal care have occurred, all the children in the neonatal intensive care unit during 1982 and 1986 should have been evaluated concerning clinical characteristics, nutrition, and neonatal morbidity. This information is available in the neonatal charts and is unrelated to how many children were later followed up. In the event that this is not done, the neonatal variables of those followed up should at least be compared with the neonatal variables of those unavailable for follow-up.

I do not see how the authors could have based their conclusion on a follow-up of less than one third of a neonatal intensive care unit cohort at 1 year of age. The experience of most neonatal intensive care units is that with the increased survival of extremely-low-birth-weight infants, morbidity, including chronic lung disease, has increased from 1982 to 1986. The authors found the opposite. These conclusions might be related to the fact that the total neonatal intensive care unit population was not analyzed and the follow-up rate was so poor.

Cleveland, OH 44106

1. Georgieff MK, Mills MM, Lindeke L, Iverson S, Johnson DE, Thompson TR. Changes in nutritional management and outcome of very-low-birth-weight infants. *AJDC*. 1989;143:82-85.

In Reply.—Dr Hack's first point, regarding providing hospitalization data on all very-low-birth-weight infants, including those not seen on follow-up, does not pertain to the interpretation

of our study results. As stated in the report, the purpose of our study was to assess growth differences at follow-up between two cohorts of infants with similar size and degree of illness who were treated 4 years apart. As described in Table 1 of the report, the cohorts were carefully matched for gestational age, weight, and degree of illness at presentation. Presentation of data on infants not subsequently seen on follow-up would serve no useful purpose in elucidating the neonatal factors that influenced follow-up growth rates of those seen.

The second point, regarding the low follow-up rate at 1 year, was a difficult one during analysis of the study results. We carefully stated in the report that there might be selection bias in those children who returned at 1 year, and that the 1-year results of the two groups may not be strictly comparable. We acknowledged the difficulty in interpreting such potentially misrepresentative low numbers in the last paragraph of the "Results" section. We used this as a rationale to combine the 12 months' corrected age data from the two age groups to demonstrate the poor developmental outcome associated with poor growth. Dr Hack has reported a similar association.¹

Finally, Dr Hack is concerned that our very-low-birth-weight infants' morbidity rates are improving at a time when others are documenting an opposite trend. She attributes this trend to greater survival rates of increasingly smaller and gestationally younger infants. While this may certainly be the case, the point is moot with respect to our study because the two groups of infants were of equivalent birth weights, gestational ages, and degree of illness. With degree of prematurity and illness between the two groups controlled for, we were able to show the significant improve-

ments in in-hospital growth and follow-up growth in the 1986 group.

Lack of Associated Renal Anomalies in Familial Polythelia

Sir:—Recent articles have addressed the possible association of supernumerary nipples with renal anomalies. Kenney et al,¹ examining Israeli infants, and Mimouni et al,² examining American term neonates, demonstrated no associated renal anomalies with isolated supernumerary nipples. However, Hersh et al³ examined dysmorphic American children and Varsano et al⁴ examined Israeli children referred to an emergency department. They demonstrated associated renal anomalies in 11% and 23%, respectively, of those children with a supernumerary nipple. A recent study by Meggyessy and Mehes⁵ demonstrated renal abnormalities in 6 (8%) of 78 Hungarian patients hospitalized for illnesses unrelated to the urinary tract and healthy newborn infants.

A limited number of instances of familial polythelia have been reported. Hersh et al³ described two parent-child pairs with polythelia. Klinkerfuss⁶ found polymastia with inconsistent polythelia in five females in four generations.

Patient Report.—We report a case of an American family of four (father, aged 31 years; mother, aged 34 years; and two sons, aged 3 years and 5 years), all of whom were found on routine examination to have left-sided supernumerary nipple. In all of these patients, the supernumerary nipple was located along the embryologic milk line approximately 3 cm inferior to the normal nipple. There was no evidence of accessory breast tissue in any member of the family. Accessory areolae were present in the mother and father but not in the children. There was no additional family history of polythelia. All of the family members were without any history suggestive of underlying renal anomalies and, similarly, were without any evidence of additional congenital anomalies. The results of renal ultrasound procedures performed on all four family members were normal.

Comment.—This study of familial polythelia as a single congenital anomaly does not support an association with either clinically overt or occult renal anomalies.

Instructions for Authors

NEW MANUSCRIPT PROCEDURE

On Jan 1, 1988, *AJDC* initiated a new procedure. Manuscripts submitted to *AJDC* will NO LONGER BE RETURNED, except in the case of accepted manuscripts or those undergoing author revision. Original artwork and photographs will be returned.

General Information.—Please send manuscripts and correspondence by first-class mail (do not use registered, certified, or express mail) to the Editor, Vincent A. Fulginiti, MD, *AJDC*, Dean's Office, Room 1529, Tulane University, School of Medicine, 1430 Tulane Avenue, New Orleans, LA 70112. All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Reprints are shipped six to eight weeks after publication. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Conforming with all of the steps listed below will facilitate the editorial processing of your manuscript.

Step 1.—Cover Letter.—All manuscripts must be accompanied on submission by a cover letter giving the name, address, affiliation, and telephone number of the corresponding author. The letter must include ALL of the following statements. SIGNED BY ALL AUTHORS (ORIGINAL SIGNATURES):

1. **Copyright Release.**—“In consideration of the American Medical Association's taking action in reviewing and editing this submission, the author(s) undersigned hereby transfer(s), assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that this work is published by the AMA.”

2. **Statement of Affirmation.**—“This manuscript has not been published anywhere in any language and is not under simultaneous consideration by another publication. This manuscript is original and ALL authors have seen and approve of its contents.”

3. **Financial Disclosure.**—List all affiliations with or financial involvement in organizations or entities with a direct financial interest in the subject matter or material of the research discussed in the manuscript (eg, employment consultancies, stock ownership) OR include a statement disclaiming any such involvement. All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosures appropriate for publication. All accepted manuscripts become the permanent property of the publisher (AMA) and may not be published elsewhere without written permission from the AMA. After publication certain articles may appear in translation in the foreign-language edition(s) of *AJDC*.

Step 2.—Manuscript Format.—All articles submitted should have the following features:

1. Four copies of the manuscript should be submitted; three are for transmission to referees and one is to be retained in the editorial office. We prefer an original and three copies.

2. Manuscripts should be typed in triple-spaced format on heavy-duty white bond paper, 21.6 × 27.9 cm (8½ × 11 in) with 2.5-cm (1-in) margins. Do not use justified right margins.

3. Title should be no more than 75 characters.

4. Authors should be limited to six, all of whom have contributed to the study and manuscript preparation, are familiar with its substance, and are able to defend its conclusions.

5. The title page should give full names, degrees, and academic affiliations of all authors, address for request of reprints, and, if the manuscript was presented at a meeting, the organization, place, and exact date on which it was read.

6. Writing style should conform to proper English usage and syntax; consult the *American Medical Association Manual of Style*, available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202.

7. Abstract should be limited to 135 words or less.

8. Each table should be typed, with a title, on a separate sheet of paper, with each line, including headings, double-spaced. Continuations should be on a second sheet with all headings repeated.

9. Use *Système International* (SI) measurements throughout the manuscript.

10. Illustrations should be high-contrast, glossy prints, in quadruplicate, unmounted and untrimmed; lettering should be legible after reduction to column size. Figure number, name of first author, and arrow indicating “top” should be typed on a gummed label and affixed on the back of each illustration. Do not write directly on the print.

Magnification and stain should be provided for histologic sections. Full-color illustrations should be submitted as 35-mm, positive color transpar-

encies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies or color prints. Fee is \$400 for up to six square-finished color illustrations that fit on one page. A letter of intent to pay the fee must accompany submission.

All photographs in which there is a possibility of patient identification should be accompanied by a signed statement of consent from both parents (or guardians). Covering eyes to mask identity is not sufficient.

11. References should be listed in order of their appearance in the text, type double-spaced, and in AMA format. Please follow the exact order of information and punctuation in the examples below.

Journal Articles: Sell EJ, Gaines JA, Gluckman C, Williams E. Persistent fetal circulation: neurodevelopment outcome. *AJDC*. 1985;139:25-28.

Books: Krmpotic-Nemanic J, Kostovics I, Rudan P. Aging changes of the form and infrastructure of the external nose and its importance in rhinoplasty. In: Conly J, Dickinson JT, eds. *Elastic and Reconstructive Surgery of the Face and Neck*. New York, NY: Grune & Stratton; 1972:84-91.

Unpublished data, personal communications, or manuscripts “in preparation” or “submitted” should not be included in the list of references. Such material, if essential, may be incorporated in the body of the article.

Authors are responsible for the accuracy of the references.

12. Investigations involving human subjects require a specific statement in the “Methods” section that an appropriate institutional review board approved the project and/or that informed consent was obtained from both legal guardians and/or child, if appropriate.

13. Illustrations and tables from other publications should be suitably acknowledged, with written permission from publisher and author. Brief acknowledgements to specific contributors directly involved in the content of the manuscript may be placed at the end of the text, before the references. General acknowledgements will be deleted.

Step 3.—Special Departments.—Criteria for several special departments are given below.

1. **The Pediatric Forum.**—This is the place for comment, criticism, observations, and discussion of “issues of current concern and importance for children's health,” in addition to letters that comment on articles in previous issues of *AJDC*. The Editor reserves the right to conduct review of and to edit all submissions. THE READER SHOULD SUBMIT TRIPLE-SPACED COPY CLEARLY MARKED “FOR PUBLICATION” AND SIGNED BY ALL AUTHORS. REFERENCES, IF INCLUDED, SHOULD CONFORM TO THE USUAL AMA FORMAT. Copyright assignment, signed by all authors, must accompany the original submission.

2. **From Research to Relevance.**—PURPOSE: To focus on significant research that has a high probability of being translated into clinical usefulness.

3. **Educational Interventions.**—PURPOSE: To share information concerning any educational efforts in the broad field of pediatrics.

4. **Sports Medicine.**—PURPOSE: To provide current information related to the medical needs of young athletes, as pertinent to counseling young athletes and their parents regarding sports participation and practices contributing to the health maintenance of the athlete, as well as current concepts in the prevention, diagnosis, and treatment of sports-related illnesses and injuries.

5. **Picture of the Month.**—Submissions should be sent directly to Murray Feingold, MD, National Birth Defects Center, Kennedy Memorial Hospital, 30 Warren St, Brighton, MA 02135, and should conform to the format for original articles in terms of the text, references, and illustrations.

6. **Radiological Case of the Month.**—Submissions should be sent directly to Beverly P. Wood, MD, University of Rochester Medical Center, 601 Elmwood Ave, PO Box 648, Rochester, NY 14642. Submissions should conform to the format for original articles in terms of the text, references, and illustrations.

Author's Checklist

- ____ 1. Cover letter with name, address, and telephone number of corresponding author.
- ____ 2. Copyright transmittal, affirmation, and financial statements signed by ALL authors.
- ____ 3. Original typed manuscript plus three copies.
- ____ 4. Triple-spacing; double-spacing for tables and legends.
- ____ 5. Right margins UNJUSTIFIED.
- ____ 6. Title 75 characters or less.
- ____ 7. Abstract included.
- ____ 8. References in proper format, cited in numerical order.
- ____ 9. Four sets of illustrations.
- ____ 10. Four sets of legends for illustrations.
- ____ 11. Proper consent forms for patient photographs.
- ____ 12. Permission forms for illustrations previously published elsewhere.

Informed Consent and the Need for Delegalization

Dr Jeffrey R. Botkin,¹ in his article "Informed Consent for Lumbar Puncture," which appears in this issue of *AJDC*, provides physicians with an adequate legal definition of the concept of "informed consent." While I might, on technical grounds, have some objections to the way he describes the exceptions to the requirement for informed consent (see below), I think his articulation of the general principles is useful. Unfortunately, informed consent is not a concept with unvarying meaning. It is used in many

See also p 899.

different contexts and has many different meanings, depending on the court or commentator who is attempting to use the phrase. The two words, however, have generally accepted contextual meaning. Thus, "informed" means knowing, understanding, or aware. It does not mean the mere telling of fact, particularly when that information is not understood by the recipient. Thus, if I give the information in a language that is not understood by the recipient, the "telling" of the information does not constitute "informing" within the meaning of the phrase. The word "consent" means an act of free will not done under duress or force. Thus, to speak of informed consent in regard to complicated medical procedures that are not easily understood by a layman is a contradiction in terms, just as to talk about the informed consent of someone who is incapable of exercising free will is equally inappropriate. Informed consent is a great deal more than simply executing a legal document. Indeed, the phrase is so overused that it has lost all legally significant meaning.

From a medical point of view, informed consent is thought to be an important component of the resolution

of any number of medical/scientific problems. Several of these problems follow:

1. Providing medically routine care to competent adult patients. Here the consent is most often implied rather than expressed.

2. Providing medically routine but somewhat risky care to competent adult patients. Here the consent is apt to take the form of some intelligent discussion between the physician and patient but may still be undocumented.

3. Providing nonroutine and high-risk care to competent adults. Here the consent is apt to take some formal form that documents the disclosure of risk and the patient's consent.

4. Providing care of all of the above to incompetent adults and children. Here, the consent, in whatever form, must be obtained from a surrogate and is more likely to be documented.

5. Securing consent in experimental programs where the advance of scientific knowledge is the primary goal rather than the provision of care to individual patients. Here the documentation of consent is likely to be extensive and formal.

6. Withdrawing care from patients whose life is likely to be near its end. Here the consent must be very formal and well documented. This is particularly so when the consent is given in advance by way of such means as a living will or a durable power of attorney.

It is a mistake to believe that some vague concept of informed consent is the answer to all these very different problems. The vastness and scope of the literature on the topic (for example: Note, Appointing an Agent to Make Medical Treatment Choices, 84 Colum L Rev 985 [1984]; Macklin, Some Problems in Gaining Informed Consent From Psychiatric Patients, 31 Emory L J 345 [1982]; Bolland, The

Doctrines of Lack of Consent and Lack of Informed Consent in Medical Procedures in Louisiana, 45 Louisiana L Rev 1 [1984]; Gelfand, Living Will Statutes: The First Decade, 1987 Wisconsin L Rev 737 [1987]), the studies and commissions that have focused on the problems,² and the expressed concern of the physicians on the front line demonstrate the complexity of the concept. In short, it is clear that a recent legal commentator was straight on the mark when she noted the "polar viewpoints" that exist on the topic (Macklin, Some Problems in Gaining Informed Consent from Psychiatric Patients, 31 Emory L J 3456 [1982]).

The tragic story of Mary O'Conner highlights the issue. In her case last fall, the highest court in New York held that a hospital had the duty to force-feed an elderly, mentally incompetent patient who was unable to eat or drink without medical "assistance," in spite of the fact that her daughters, under oath, swore that their mother had "repeatedly stated that she did not want her life prolonged by artificial means if she was unable to care for herself." In so doing, the court established a standard that will be impossible to meet in the vast majority of cases. The court held that Mary O'Conner's consent had to be proved by "clear and convincing" evidence of a "settled and firm commitment" to natural death. Moreover, the court held that the trier of fact had to be convinced of the continued vitality of the commitment "as far as humanly possible." Judge Simons, in dissent, noted the inevitable consequences of the court's pronouncement:

... these new requirements will undoubtedly increase litigation in this area because medical and hospital personnel, fearful of civil and criminal liability, will hesitate to honor patients' wishes without judicial approval.

It seems clear that the O'Conner de-

cision will have effects far beyond its facts. It will be applied, rightly or wrongly, to many areas where informed consent is thought to be required. It may mark a reversal of the trend toward a notion of "reasonable consent," where common sense and human values hold sway over legal technicalities. Whatever the decision does, it will generate further confusion about the legal consequences of providing health care.

In an ideal and moral world, the decision to allow Mary O'Conner to die a peaceful and dignified death would not be a matter for the courts. Caregivers would not fear retribution for exercising moral and medical judgment. Families would be consulted and judgments made in privacy without the glare of judicial intervention. However, that world no longer exists. Today, medical technology and law have combined to create a world where morality and human privacy are rele-

gated to a minor, if not inconsequential, role.

To restore the primacy of human values requires bold action by the medical and legal professionals who must live day to day with consequences of overlegalization and judicial intervention in private decision making. The legislature has the power to largely remove the courts from this process and I believe it should do so. We need to "delegalize" the notion of informed consent and provide by statute for a sphere of protected decision making, where patients and physicians can exercise judgment about health care decisions that will not be second guessed. Such an undertaking would bring great benefits to all concerned and it is, in my estimation, an achievable goal. It will require hard choices and the undertaking of risk. The end result, however, would be a more humane and functional process for the making of health care deci-

sions.

By statute, we can restore the primacy of individual decision making and the morality of private choice. If we continue with the case-by-case decision-making process that we have followed for the last few decades, we will sink ever further into a morass of legalisms that ill serve the needs of health care professionals, patients, and society.

Chronic Sinusitis

The Disease of All Ages

Sinusitis is one of the most frequently overlooked and poorly understood diseases of childhood. There is a lack of information regarding criteria for diagnosis and the most effective method of management of sinusi-

See also p 938.

tis in children. Controversy exists regarding whether a sinus cavity is infected, how to diagnose sinusitis, and what the best treatment choice and duration is. The article by Tinkelman and Silk¹ in this issue of *AJDC* has prompted this editorial to bring

the pediatrician up to date regarding these issues. I will limit my remarks to chronic sinusitis, that is, compatible symptoms that have been present for at least 3 weeks. (Some experts in the field would shorten this time to 10 days.^{2,3})

The nasal sinuses are four paired structures: the maxillary, ethmoidal, sphenoidal, and frontal sinuses that develop as evaginations of the mucous membranes of the nasal meatuses. The origin of the ethmoid and maxillary sinuses is apparent by the third to fifth month of intrauterine life, and air is apparent in these sinuses shortly

after birth. Thus, sinusitis *can occur at any age and is not limited* to children over 5 years of age. The frontal sinuses appear radiographically by the seventh year, the sphenoids by the ninth year. The sinuses seem to function as organs to warm and humidify inhaled air, secrete mucus, capture foreign airborne particles and remove them from inspired air, increase olfactory sensitivity, impart resonance to the voice, and act as shock absorbers.

The sinuses rely on mucociliary clearance for drainage. The blanket of mucus helps in defense against sinus infections. Mucociliary action directs

the mucus and its trapping to the sinus ostia that opens into the nose. Obstruction in the region of the osteomeatal complex can produce obstruction and subsequent disruption of the involved sinus. Ciliary and mucous blanket function is disturbed and local resistance factors are diminished, resulting in accumulation of mucous secretions and inflammation with subsequent bacterial contamination.

The major factors implicated in the initiation of this process are viral upper respiratory tract infection and allergic rhinitis. Other factors include swimming, abuse of topical nasal decongestants, immune deficiency (especially selective IgA deficiency), and structural abnormalities. About 40% of children with chronic sinusitis have allergic rhinitis.

The diagnosis of chronic sinusitis is made by medical history and physical examination and is supported by roentgenographic findings, with the medical history usually providing a strong index of suspicion. The predominant symptom of chronic sinusitis is night and day coughing; there also may be nasal obstruction, nasal discharge, postnasal drip, sore throat, and fetor oris. Nasal symptoms may be minimal or absent. Fever and headache are uncommon. If the patient also has asthma, it is often harder to control when there is concomitant chronic sinusitis, and in these patients, sinusitis may be the only trigger of asthma. In this case, treating the sinusitis will decrease or eliminate the asthma.

The cough usually begins shortly after lying down at night, lasting for 1 to 2 hours and then resuming early in the morning and sometimes (10%, in my experience) it is associated with vomiting. Up to 60% of children with chronic sinusitis will have associated middle-ear disease. Fatigue, malaise, decreased appetite, and weight loss are associated complaints. Parents usually complain of a "cold" that never went away or a cough that is hard to control.

Physical examination reveals rhinorrhea, a red boggy nasal mucosa, postnasal drip, erythema, and cobblestoning in the posterior pharynx, with swelling of the lateral lymphoid

tissue. The nasal drainage can vary; it may be absent or diffuse, the color may be clear, yellow, or green, and the consistency may vary from thin to thick. Therefore, do not rely on the color to make a diagnosis of sinusitis.

Diagnostic aids commonly used are cytologic examination of nasal secretions, roentgenography, transillumination, and ultrasonography. Because nasal cultures are contaminated with other organisms, they do not give an adequate picture of the organisms responsible for sinusitis and therefore should not be done. The peripheral white blood cell count and the differential cell count as well as the erythrocyte sedimentation rate are of value only in the child with acute sinusitis.

Fresh nasal secretions with a large number of polymorphonuclear cells, especially with intracellular bacteria, is a frequent finding. While these cells may be seen during a viral upper respiratory tract infection, their presence in large numbers in a profuse rhinorrhea of several weeks' duration suggests sinusitis. In the child with allergic rhinitis, this nasal smear will have polymorphonuclear cells and not eosinophils. An abnormal nasal smear finding is sensitive but not a very specific predictor of sinusitis in the allergic child.

A good roentgenogram is the most reliable adjunct in the clinical diagnosis of sinusitis. Persistent chronic obstruction of the sinuses is usually associated with infection in the maxillary sinuses, even if the infection begins in the ethmoids. There are four standard views used in the roentgenographic evaluation of the paranasal sinuses: occipitomeatal (Waters), occiput frontal (Caldwell), lateral, and submentovertical. The Waters view is usually adequate, since this provides the best view of the maxillary sinuses. Diffuse opacification, mucosal thickening greater than 50% of the antrum (usually 4 to 6 mm or more), or an air-fluid level is considered diagnostic of a bacterial infection. Although there may be active infection with less prominent mucous membrane thickening, the correlation with culture evidence for infection and/or response to antimicrobial drugs is weaker. In these instances, the total clinical picture and

clinical judgment should dictate therapy. Allergic or vasomotor rhinitis do not result in significant sinus mucosal thickening. In my experience and the experience of others, sinus roentgenograms are not helpful in the child under 1 year of age.⁴

A-mode ultrasound, primarily useful for the detection of retained secretion and not mucosal thickening, is not sensitive and specific enough in children to be a helpful diagnostic tool. Transillumination may be a useful screening tool in adults but is not useful in detecting sinusitis in children. The role of computed tomographic scanning and magnetic resonance imaging has not been evaluated in children. Crying does not result in abnormal roentgenograms.

Most studies on the bacterial causes of sinusitis have involved adults. In acute sinusitis in children, *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Branhamella catarrhalis* are the major organisms. Studies of chronic sinusitis in children are limited. Brook⁵ (40 patients) demonstrated anaerobic organisms, including *Bacterioides* species, α -hemolytic streptococci, *Staphylococcus aureus*, and *Haemophilus* species, while a study of 8 children⁶ revealed *B catarrhalis*, *H influenzae*, and *S pneumoniae*.

Tinkelman and Silk demonstrated that 22 of 35 children with chronic sinusitis had positive bacterial cultures of the sinus aspirate, with 19 of the 22 children being under the age of 5 years. The most common organisms isolated were *H influenzae*, *S pneumococcus*, and *B catarrhalis*. They reported that 5 of 8 *S pneumococci* organisms recovered were relatively resistant to penicillin. Anaerobic organisms were not isolated. There are several problems with their study, including its retrospective design, the lack of clinical data on the children (ie, truly allergic vs nonallergic), and the involvement of four hospitals indicating the likelihood that techniques may have varied from place to place and time to time. In particular, how much credence can we place in the statement that all air was expelled from the syringes and that all cultures were set up within 30 minutes of collection?

Anaerobic transport setups could have been better, and most laboratories would have incubated the chocolate agar under 10% carbon dioxide. They should have used a nonselective anaerobic medium. These points and prior therapy could have accounted for the lack of recovery of anaerobes. All of the patients were receiving antibiotic therapy (and repeated courses) at the time of specimen collection; this would limit the number of positive cultures and account for the relatively resistant organisms. Apparently specimens were only taken during the maxillary punctures, not during the surgical procedures; the latter would have provided better specimens. I would like to know why so many antral windows were done since this is an uncommon procedure in children, especially during the first surgical intervention. In addition, minimum inhibitory concentrations with penicillin and the pneumococci would have been most helpful.

We recently completed a study of 12 children (3 to 9 years of age) with allergic rhinitis complicated by chronic maxillary sinusitis.⁷ Sinus aspiration/irrigation culture results revealed a pure growth of *B. catarrhalis* in 5 of 12 patients, four of which were β -lactamase positive. The cultures of 4 patients yielded mixed species (one mixed *Branhamella* and streptococcal species and three mixed streptococcal species). Three patients' sinus cultures yielded no organisms. The study demonstrated clinical improvement even in patients with negative cultures, ie, just evacuating the maxillary sinus was exceedingly helpful.

The management of chronic sinusitis must be directed to the known bacteriology of this disease. More studies are necessary. However, my recommendation would be a trial of an antimicrobial agent(s) (amoxicillin with clavulanic acid), an oral cephalosporin (cefuroxime or cefaclor), or erythromycin and a sulfonamide (given together or as full separate daily doses) for a period of 2 or 3 weeks. If there is no clinical response, then another antimicrobial agent from this group is given for 3 more weeks. Clinical response usually occurs within 5 days, with decreased cough, less rhinor-

rrhea, and improved well-being. If clinical and laboratory response is inadequate, I strongly urge consideration of mechanical sinus aspiration and lavage with appropriate culture and antimicrobial therapy appropriate for the organism recovered. The role of endoscopic surgery and the treatment of the osteomeatal complex at this stage of a child's chronic sinusitis needs to be evaluated further. The initial reports suggested that the endoscopic approach might be more effective than just the plain mechanical aspiration and lavage of the sinuses. I do not repeat sinus roentgenograms if there is a clinical response; I usually do them again if (1) I'm considering surgical intervention, (2) the child has had frequent clinical sinusitis with brief "well" periods while not receiving antibiotic therapy, or (3) the asthma (if present) continues to be a management problem.

I do not recommend an antral window unless the antral lavage needs to be repeated within a 6-month period. My experience is that less than 2% of children need to have repeated surgical intervention in so short a time. Approximately 10% of my patients will need another lavage. These children usually have IgA deficiency or poorly controlled allergic rhinitis. Adenoidectomy is of uncertain benefit in the prevention or treatment of chronic sinusitis. However, if postnasal obstruction is present, adenoidectomy will improve the nasal airway. Some children will have bacterial infection of the adenoids, the source of chronic or repeated airway infection.

The role of antihistamines, decongestants, nasal cromolyn sodium, and nasal corticosteroids has not been evaluated in children with chronic sinusitis. The nonallergic child, without a predisposing factor, with recurrent sinusitis sometimes benefits from the antiinflammatory effects of either or both topical medications. The child with allergic rhinitis needs to have the allergic disorder treated properly, or the sinusitis will become recurrent. Such management should include environmental control, the avoidance of cigarette smoke and swimming, medication, and, at times, immunotherapy. I have been impressed with topical

therapy (cromolyn sodium or corticosteroids) in such children and it should be continued for a minimum of 6 months. I sometimes combine medications and have initiated one or both therapies in children under 5 years of age.

My colleagues and I are impressed by the number of sufferers of chronic rhinitis we see whose presentation is bacterial sinusitis. Many of these children have had recurrent chronic middle-ear disease that does not improve until the sinus disease is improved or cured. We have seen many children under the age of 2 years with this problem. The report by Timan and Silk also has demonstrated this. We are impressed with the number of children with asthma who have difficult-to-control airways and do not respond to proper management including corticosteroid therapy, the underlying sinusitis is recognized and treated.

Now that sinusitis is a recognized and acceptable disorder in children of all ages, it is important to study true incidence, modes of therapy, and reasons it occurs.

When I was a child there was no Orimune®

Poliovirus Vaccine Live Oral Trivalent

Jackie DiLorenzo of Hastings-on-Hudson, New York, contracted polio in 1950, before a vaccine became available. She spent ten years in rehabilitation, during which time she underwent nine operations on her spine, legs and feet. Jackie currently lives in a house adapted for wheelchair living.

Lederle Biologicals Protecting Families Through Immunization®

Please see following page for brief summary of prescribing information.

about the award-winning
Adolescent Wellness Program

When I was a child there was no Orimune®

Proven in Millions of US Patients

ORIMUNE was the first live, oral, trivalent polio vaccine. No other oral polio vaccine has done more to help eradicate wild poliovirus in the US. Over 500 million doses have been distributed to date.

Proven Safety* Record

Lederle takes every precaution during production and testing to ensure the safety of ORIMUNE. This dedication is evident by our 27-year safety record.

Uninterrupted Supply

Lederle has consistently met the nation's needs for oral polio vaccine for about 27 years. In fact, when all other US manufacturers discontinued the production of oral polio vaccine, Lederle has remained committed to this essential product and to the health of America's children.

Available in Single-Doses

ORIMUNE is available in convenient, unit-dose DISPETTES® to help assure dosage accuracy and avoid the risk of contamination.

*Paralytic disease following ingestion of live poliovirus vaccine has been reported on rare occasions in individuals receiving the vaccine or in their close contacts.

Poliovirus Vaccine Live Oral Trivalent ORIMUNE®

A Brief Summary

Please see package insert for full description, directions for use, and references.

INDICATIONS: For prevention of poliomyelitis caused by Poliovirus Types 1, 2, and 3.

CONTRAINDICATIONS: Under no circumstances should this vaccine be administered parenterally.

Administration of the vaccine should be postponed or avoided in those experiencing any acute illness and in those with any advanced debilitated condition or persistent vomiting or diarrhea.

ORIMUNE must not be administered to patients with immune deficiency diseases such as combined immunodeficiency, hypogammaglobulinemia, and agammaglobulinemia. It would also be prudent to withhold ORIMUNE from siblings of a child known to have an immunodeficiency syndrome or from children in a family which has a history of immunodeficiency until immune status of all members is determined. Further, ORIMUNE must not be administered to patients with altered immune states, such as those occurring in thymic abnormalities, leukemia, lymphoma, or generalized malignancy or by lowered resistance from therapy with corticosteroids, alkylating drugs, antimetabolites, or radiation. All persons with altered immune status should avoid close household-type contact with recipients of the vaccine for at least six to eight weeks. Inactivated poliovirus vaccine (IPV) is preferred for immunizing all persons in the above described circumstances.

WARNINGS: Under no circumstances should this vaccine be administered parenterally.

Administration of the vaccine should be postponed or avoided in those experiencing any acute illness and in those with any advanced debilitated condition or persistent vomiting or diarrhea.

Other viruses (including poliovirus and other enteroviruses) may interfere with the desired response to this vaccine, since their presence in the intestinal tract may interfere with the replication of the attenuated strains of poliovirus in the vaccine.

PRECAUTIONS: It would seem prudent not to administer trivalent oral poliovaccine (OPV) shortly after Immune Globulin (IG) unless such a procedure is unavoidable. For example, with unexpected travel to or contact with epidemic areas or endemic areas. If OPV is given with or shortly after IG, the dose probably should be repeated after three months if immunization is still indicated.

The vaccine is not effective in modifying or preventing cases of existing and/or incubating poliomyelitis.

Use in Pregnancy: Pregnancy Category C: Animal reproduction studies have not been conducted with Poliovirus vaccine live oral trivalent. It is also not known whether OPV can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Although there is no convincing evidence documenting adverse effects of either OPV or IPV on the developing fetus or pregnant woman, it is prudent on theoretical grounds to avoid vaccinating pregnant women. However, if immediate protection against poliomyelitis is needed, OPV is recommended. (See CONTRAINDICATIONS and ADVERSE REACTIONS.)

ADVERSE REACTIONS: Paralytic disease following the ingestion of live poliovirus vaccines has been, on rare occasion, reported in individuals receiving the vaccine (see, for example, CONTRAINDICATIONS), and in persons who were in close contact with vaccinees. The vaccine viruses are shed in the vaccinee's stools for at least six to eight weeks as well as via the pharyngeal route. Most reports of paralytic disease following ingestion of the vaccine or contact with a recent vaccinee are based on epidemiological analysis and temporal association between vaccination or contact and the onset of symptoms. Most authorities believe that a causal relationship exists. Prior to administration of the vaccine, the attending physician should warn or specifically direct personnel acting under his authority to convey the warnings to the vaccinee, parent, guardian, or other responsible person of the possibility of vaccine-associated paralysis, particularly to susceptible family members and other close personal contacts. The Centers for Disease Control report that during 1972 to 1983, approximately 278.8 million OPV doses were distributed in the United States. During this same period, 87 vaccine-associated cases in apparently immunologically normal individuals were reported. Thirty-two occurred among vaccine recipients (one case per 8.7 million OPV doses distributed), and 55 cases occurred among household and nonhousehold contacts of vaccinees (1 case per 5.1 million doses distributed). Sixteen other vaccine-associated cases have been reported in persons (recipients or contacts) with immune deficiency conditions.

Because the number of susceptible vaccine recipients or contacts of recipients is not known, the true risk of vaccine-associated poliomyelitis is impossible to determine precisely.

When the attenuated vaccine strains are to be introduced into a household with adults who have not been adequately vaccinated or whose immune status cannot be determined, the risk of vaccine-associated paralysis can be reduced by giving these adults one dose of IPV per month for three months before the children receive Poliovirus vaccine live oral trivalent ORIMUNE. The children may receive the first dose of ORIMUNE at the same visit that the adult receives the third dose of IPV. The CDC reports that no paralytic reactions to IPV are known to have occurred since the 1955 cluster of poliomyelitis cases caused by vaccine that contained live polioviruses that had escaped inactivation.

The ACIP states: "Because of the overriding importance of ensuring prompt and complete immunization of the child and the extreme rarity of OPV-associated disease in contacts, the Committee recommends the administration of OPV to a child regardless of the poliovirus-vaccine status of adult household contacts. This is the usual practice in the United States. The responsible adult should be informed of the small risk involved. An acceptable alternative, if there is a strong assurance that ultimate, full immunization of the child will not be jeopardized or unduly delayed, is to immunize adults according to the schedule outlined above before giving OPV to the child."

The ACIP has concluded that "Oral polio vaccine remains the vaccine of choice for primary immunization of children."

Tavist[®] Syrup
(clemastine fumarate) 0.67 mg/5 ml

**Lets kids be kids
12 hours long**

BRIEF SUMMARY

AVIST®

(clemastine fumarate) SYRUP 0.5 mg/5 ml
 (present as clemastine fumarate 0.67 mg/5 ml)

INDICATIONS AND USAGE

Avist® (clemastine fumarate) Syrup is indicated for the relief of symptoms associated with allergic rhinitis such as sneezing, rhinorrhea, pruritus and lacrimation. Tavist® (clemastine fumarate) Syrup is indicated for use in pediatric populations (ages 6 years through 12) and adults (see **DOSAGE AND ADMINISTRATION**).

It should be noted that Tavist® (clemastine fumarate) is indicated for the relief of mild, uncomplicated allergic skin manifestations of urticaria and angioedema at the 2 mg dosage level only.

CONTRAINDICATIONS

Antihistamines are contraindicated in patients hypersensitive to the drug or to other antihistamines of similar chemical structure (see **PRECAUTIONS — Drug Interactions** in a complete package insert).

Antihistamines should not be used in newborn or premature infants. Because of the higher risk of antihistamines for infants generally and for newborns and premature infants in particular, antihistamine therapy is contraindicated in nursing mothers (see **PRECAUTIONS — Nursing Mothers** in a complete package insert).

WARNINGS

Antihistamines should be used with considerable caution in patients with: narrow angle glaucoma, stenosing peptic ulcer, prostatic hyperplasia, symptomatic prostatic hypertrophy, and bladder neck obstruction.

Use with CNS Depressants: Tavist® (clemastine fumarate) has additive effects with alcohol and other CNS depressants (sedatives, tranquilizers, etc.).

Use in Activities Requiring Mental Alertness: Patients should be warned about engaging in activities requiring mental alertness such as driving a car or operating appliances, machinery, etc.

Use in the Elderly (approximately 60 years or older): Antihistamines are more likely to cause dizziness, sedation, and potentiation in elderly patients.

ADVERSE REACTIONS

The most frequent adverse reactions are underlined:

Nervous System: Sedation, sleepiness, dizziness, disturbed coordination, fatigue, confusion, restlessness, excitation, nervousness, tremor, irritability, insomnia, euphoria, paresthesia, blurred vision, diplopia, vertigo, tinnitus, acute labyrinthitis, hysteria, neuritis, convulsions.

Gastrointestinal System: Epigastric distress, anorexia, nausea, vomiting, diarrhea, constipation.

Respiratory System: Thickening of bronchial secretions, tightness of chest and wheezing, nasal stuffiness.

Cardiovascular System: Hypotension, headache, palpitations, tachycardia, extrasystoles.

Hematologic System: Hemolytic anemia, thrombocytopenia, granulocytosis.

Genitourinary System: Urinary frequency, difficult urination, urinary retention, early menses.

General: Urticaria, drug rash, anaphylactic shock, photosensitivity, excessive perspiration, chills, dryness of mouth, nose and throat.

DOSAGE AND ADMINISTRATION

DOSAGE SHOULD BE INDIVIDUALIZED ACCORDING TO THE NEEDS AND RESPONSE OF THE PATIENT.

Pediatric: Children aged 6 to 12 years

For Symptoms of Allergic Rhinitis — The starting dose is 1 teaspoonful (0.5 mg clemastine) twice daily. Since single doses up to 2.25 mg clemastine were well tolerated by this age group, dosage may be increased as required, but not to exceed 3 teaspoonsful daily (3 mg clemastine).

For Urticaria and Angioedema — The starting dose is 2 teaspoonsful (1 mg clemastine) twice daily, not to exceed 6 teaspoonsful daily (3 mg clemastine).

Adults and Children 12 Years and Over

For Symptoms of Allergic Rhinitis — The starting dose is 1 teaspoonful (1 mg clemastine) twice daily. Dosage may be increased as required, but not to exceed 12 teaspoonsful daily (3 mg clemastine).

For Urticaria and Angioedema — The starting dose is 4 teaspoonsful (2 mg clemastine) twice daily, not to exceed 12 teaspoonsful daily (6 mg clemastine).

HOW SUPPLIED

Avist® (clemastine fumarate) Syrup

Clemastine 0.5 mg/5 ml (present as clemastine fumarate 0.67 mg/5 ml). A clear, colorless liquid with a citrus flavor, in 4 fl. oz. bottle (NDC 0078-0222-31).

Rubella and Congenital Rubella Syndrome—United States, 1985–1988

RUBELLA

A provisional total of 221 cases of rubella was reported in the United States in 1988 (0.1 cases per 100,000 population), the lowest since rubella became a nationally notifiable disease in 1966. The incidence of rubella has declined by more than 99% since 1969, the year rubella vaccine was licensed.

In 1987, the last year for which complete data are available, 20 of 52 reporting areas (which comprise the 50 states, District of Columbia, and New York City [NYC]) reported no rubella cases, compared with 18 reporting areas in 1986 and 14 in 1985. The reported age-specific incidence rates of rubella declined for all age groups during these 3 years.

Long-term trends of rubella incidence among specific age groups can be assessed by comparing recent data from the total United States with those from three areas for which age-specific data were available before 1975—Illinois, Massachusetts, and NYC. The reported incidence rates for 1985–1987 have declined by greater than or equal to 95% for all age groups, with the greatest decreases occurring among persons less than 20 years of age.

CONGENITAL RUBELLA SYNDROME

Data on congenital rubella syndrome (CRS) are available from reports submitted weekly to the MMWR and from the National Congenital Rubella Syndrome Registry (NCRSR) maintained at the Division of Immunization, Center for Prevention Services, CDC. The MMWR CRS reports are case counts with no accompanying data and are tabulated by year of report. The NCRSR contains clinical and laboratory information on cases of CRS that are reported by state and local health departments. The NCRSR cases are monitored by year of patient's birth and are classified into six clinical categories,¹ the most specific of which are "CRS-confirmed"

(i.e., cases with both congenital anomalies and laboratory evidence of rubella infection) and "CRS-compatible" (i.e., cases that satisfy selected clinical criteria without laboratory confirmation). Beginning in 1984, information was routinely collected to evaluate whether a CRS case was "indigenous" or "imported."* Since the NCRSR cases are classified by year of patient's birth, data are considered provisional for any given year; delays in diagnosis and/or reporting may result in the updating of figures. This summary updates previous reports on surveillance of CRS in the United States.¹

For infants born in 1987, six CRS cases were reported to the NCRSR, of which three were considered indigenous. All three were confirmed CRS cases, and one of them occurred in a mother who had had at least one previous pregnancy. Only one CRS case has been reported thus far for 1988. Recent declines in rates of CRS recorded by NCRSR have paralleled the decline in overall rubella incidence and, more specifically, in the incidence for persons greater than or equal to 15 years of age. During 1970–1987, the reported rate of rubella among persons in this age group declined 97%, from 2.3 to 0.1 cases/100,000 population. In 1970, 67 CRS cases occurred (1.80/100,000 live births), and three have been reported as of March 22, 1989, for 1987 (0.08/100,000 live births), representing a 96% decline. This downward trend was interrupted in 1986, when 12 CRS cases were reported.² In that year, eight of these cases were reported to the NYC Department of Health 8–10 months after the peak of a rubella outbreak in NYC.³

Reported by: Surveillance, Investigations, and Research Br, Div of Immunization, Center for Prevention Svcs, CDC (MMWR vol 38, No. 11).

CDC Editorial Note: As part of the 1990 health objectives for the nation, the Public Health Service set a goal to reduce the number of rubella cases to less than 1000 and to reduce CRS to

less than 10 cases annually.⁴ The former goal was achieved for the first time in 1983, when 970 rubella cases were reported.⁵ Although the goal for CRS has also been reached, unacceptable morbidity is still occurring. The primary aim of rubella vaccination programs is to prevent congenital rubella infection, which can result in miscarriages, abortions, stillbirths, and CRS in infants. When rubella vaccine was licensed in 1969, the United States adopted a policy of universal immunization of children of both sexes. The focus of this rubella vaccination strategy was to control rubella in preschool-aged and young school-aged children, the primary sources of rubella transmission. This strategy was designed primarily to reduce and interrupt circulation of the virus, thereby reducing the risk of exposure to susceptible pregnant women. Also, vaccinated children would be protected immediately, and their immunity was expected to persist at least through their childbearing years.⁶ Secondary emphasis was placed on vaccinating susceptible adolescents and adults, especially women.

The success of the rubella control program is apparent. In 1966–1987, the reported incidence rates of CRS and of rubella among persons greater than or equal to 15 years of age declined in parallel by 95%–96% to all-time low levels. Meanwhile, incidence rates of rubella in children less than 15 years of age have continued their downward trend. As the highly immune cohorts of young children enter the childbearing years, CRS should disappear from this country.

However, concern continues despite the dramatic success of the U.S. rubella immunization program. In 1987, 48% of reported rubella cases were in persons greater than or equal to 15 years of age (32% of all cases were in persons 15–29 years of age). Most serologic surveys of various postpubertal populations carried out during the 1970s and early 1980s found rates of rubella susceptibility comparable to the prevaccine years: 10%–20% of persons still lacked serologic evidence of immunity to rubella.^{7–9} Updated population-based serologic surveys are needed to fully characterize the magnitude and extent of risk for this adolescent and young adult population. The NYC experience during 1985–1986^{2,3} and several recent college outbreaks¹⁰ highlight the possible risk of disease in postpubertal women. The continued occurrence of rubella in childbearing-aged populations sug-

gests that potentially preventable cases of CRS may continue to occur during the next 10–30 years. Such concerns led CDC to announce an initiative in February 1985 to hasten elimination of rubella and CRS by targeting susceptible childbearing-aged populations for vaccination.¹¹

In addition, the reported figure for CRS cases is believed to underestimate the actual total, perhaps capturing only 10% of the actual total.¹² The NCRSR is a passive reporting system that, by its nature, results in under-reporting of actual disease incidence and selective reporting of infants with severe and obvious CRS recognized and reported early in life. The limitations of current CRS surveillance underscore the need for all specialists who treat children with congenital anomalies compatible with CRS to continue to consider it in the differential diagnosis and to report all suspected cases to their state health departments.

As with other adult immunizations, creative approaches are necessary to enhance rubella immunization levels in the childbearing-aged population. Adopting and enforcing comprehensive kindergarten through 12th grade school immunization laws (especially for postpubertal elementary and secondary school students) and requiring proof of immunity to rubella as a condition for college entry can minimize the risk of rubella outbreaks in these populations.¹³ Another way to reach

susceptible postpubertal women is to offer rubella vaccine at any encounter with the health-care system. After excluding patients who say they may be pregnant and counseling about the advisability to avoid conception for 3 months after vaccination, practitioners should not hesitate to vaccinate childbearing-aged women against rubella. No CRS-like defects have been detected in 212 infants born to susceptible mothers inadvertently vaccinated with RA27/3 live rubella virus vaccine during pregnancy (14; CDC, unpublished data). NCRSR surveillance data indicate that one third to one half of mothers delivering CRS infants had had a previous live birth, suggesting that both postpartum vaccination and use of rubella vaccine in family-planning clinics could have an important impact on the overall occurrence of reported CRS. Physicians and other health-care personnel should offer rubella vaccine whenever they encounter a potentially susceptible woman lacking contraindications for vaccination. Susceptible persons identified through preemployment, premarital, or prenatal screening should be offered vaccine at follow-up visits.

14. CDC. Rubella vaccination during pregnancy—United States, 1971–1986. *MMWR* 1987;36:457–61.

*Based on definitions approved by the Council of State and Territorial Epidemiologists, an imported case of CRS is defined as CRS in a U.S. or non-U.S. citizen whose mother was outside the United States during her presumed exposure to rubella. If the timing of exposure to rubella cannot be determined, the mother must have been outside the United States throughout the 21 days before conception and the first 20 weeks of her pregnancy.

Reye Syndrome Surveillance—United States, 1987 and 1988

FOR THE 1987 and 1988 surveillance years, 36 and 20 cases, respectively, of Reye syndrome (RS) were reported to the National Reye Syndrome Surveillance System. These years have the lowest number of cases reported since continuous national surveillance was established in December 1976. For both years, approximately 80% of reported patients had an antecedent illness within 3 weeks before onset of vomiting or neurologic symptoms. Eighteen RS patients in 1987 and nine in 1988 had respiratory illnesses; seven and four had varicella; three and two had diarrhea without respiratory symptoms. In both years, approximately 50% of cases occurred in January, February, and March—the peak months for respiratory viral infections, including varicella and influenza (type A[H1N1] in 1987 and type

A[H3N2] in 1988).

In 1987, 17 (47%) of the 36 reported RS patients and, in 1988, 16 (80%) of the 20 patients were female; 33 (92%) and 19 (95%), respectively, were white, two (6%) and one (5%) were black, and one patient (3%) in 1987 was Asian. Seventeen patients each year were greater than or equal to 5 years old, representing a 75% decline in the number of cases in this age group from 1986. Nineteen reported patients in 1987 and three in 1988 were less than 5 years old, representing a 42% and a 91% decline, respectively, in this age group from 1986.

Approximately 75% of patients in both 1987 and 1988 were admitted to hospitals in precomatose stages of RS—stages 0, 1, or 2. In each year, stage 2 was the classification for the largest number of patients upon ad-

mission (47% and 55%, respectively), followed by stage 1 for 1987 (31%) and stages 0, 1, and 3 (10% each) for 1988. In 1987, the most severe phases of illness after hospitalization were stage 1 (25%), stage 2 (8%), stage 3 (8%), stage 4 (11%), and stage 5 (30%). Eleven percent of patients received treatment that precluded classification (i.e., they had received anesthetic or paralyzing agents in their treatment); the most severe stage was not reported for 7%. In 1988, 25% reached stage 1 only; 5% reached stage 2, 20% reached stage 3, 20% reached stage 5, and 30% received treatment that precluded classification.

PEDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus var. capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus var. capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combing of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: Teratogenic Effects: Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp (especially behind the ears and on nape of the neck). Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combing of nits is not required for therapeutic efficacy, but may be done for cosmetic reasons or to meet school 'no nit' policies. A nit comb is provided.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz. weighing 56 g. (NDC-0081-0780-81)

Store at 15°-25°C (59°-77°F).

CHIEF DIVISION OF PEDIATRICS

WalthamWeston Hospital & Medical Center, a 305 bed community hospital, 11 miles west of Boston, is conducting a search for the Chief of the Department of Pediatrics. This individual would be responsible for the overall management of clinical practice and program development within the Department. This is an excellent opportunity for a qualified candidate to develop a pediatric service with the support of the medical staff and management. Candidates should be Board Certified in Pediatrics or Pediatric subspecialty. They should have a proven record as a clinician, educator, and administrator.

The Greater Boston area enjoys a lifestyle of numerous cultural, educational and recreational activities.

Please send curriculum vitae in confidence to:

of Family Violence and
Victimization**

The Editorial Board Speaks . . .

Peggy C. Ferry, MD

Dr Ferry is completing sabbatical leave from her position as professor of pediatrics and neurology at the University of Arizona, Tucson. She was a visiting scientist, Developmental Neurology Branch, Division of Convulsive, Developmental, and Neuromuscular Disorders, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Md. Her major project this year was to conduct a survey of the neurological complications and consequences of cardiac surgical procedures in infants and children. Her original work appeared in *AJDC* (1987;141:309-312). In addition, Peggy continues as our book review editor, and her long love of books stands her in good stead in this role for *AJDC*. Peggy has also published recently a tribute to Amos Christie and a commentary on the confusion attendant on new brain-death guidelines in children. She also has served as guest faculty for the Children's Hospital and Health Center in San Diego, Calif, the University of California at San Francisco, and for several of the American Academy of Pediatrics continuing education courses. She just completed a 5-year term as the neurology representative on the Committee on Scientific Meetings of the American Academy of Pediatrics.

ACUTE REMUNERATIVE NEUROLOGY

The journal ads are bright and colorful. They describe EEG and EMG equipment with trendy, catchy headings:

- "A New Dimension in Neurodiagnostics"
- "The Leading Light in EMG/Evoked Responses"
- "Now Sleep Labs Can Make House Calls"
- "Evoked Potential Technology at Your Fingertips (Learn in the morning, operate in the afternoon)"
- "The New, Mighty Navigator"

The equipment names are similarly virile—Madison Avenue at its best: one is called "NEUROSTAR"; others, "MYSTRO," "CONCERTO," and "VIKING." One unit is billed as "a complete neurodiagnostic laboratory," promising neurometric analysis, brain mapping ("see events inside your patient's brain"), ambulatory EEG recording, evoked potentials, sleep laboratory tracings, and surgical monitoring. Practitioners are exhorted to "Equip Your Practice for Under 40K!" Some ads promise that the equipment will pay for itself in "just a month." Another rejoices that the computerized diagnostic machine even "fills out insurance reports ready for you to sign." Neurologists are urged to "leverage" their expertise by buying the equipment for their offices. Toll-free numbers for further information are included; perhaps one should be 1-800-GREED.

When I was in pediatric neurology fellowship training in the 1960s, one of my teachers called the phenomenon by which neurologists generate income by performing neurodiagnostic tests themselves *acute remunerative neurology*. He decried the practice, which fortunately was fairly rare then. Am I getting old, or do recent observations suggest a reappearance of the disorder?

Residents are being encouraged to take fellowships in EEG and EMG proficiency. The majority of journal ads for neurology positions insist "EEG/EMG capability strongly advisable." Translation: we need you to generate a portion of your income by doing these procedures. One recent advertisement for a neurologist in a large city read as follows: "Candidate must demonstrate competence in EEG, EMG, evoked potentials, and CAT scan interpretation." What ever happened to the history, neurologic examination, and neuroradiologists?

The entrepreneurial spirit also carries over to continuing education. The abstract of a course at a major national neurology meeting promises to teach neurologists how to make the area of study a "financially successful enterprise."

A business column in a recent medical news magazine suggests that a good marketing strategy for physicians is to send holiday presents to referring colleagues—fruit baskets, wine, or magazine subscrip-

tions are considered "standard physician etiquette." Another article notes, "You've got to think of ways to get your name up in lights." Visitors to the opening of an MRI facility are given souvenir copies of their own head scans to commemorate the momentous occasion. That could prove interesting in the social hour that often follows ("Wow, did you catch that atrophy?").

The prospects for other income-generating avenues in neurologic practice are limitless. A few come to mind immediately for marketing to patients and colleagues:

- A Polaroid copy of your MRI scan, suitable for framing (to show to your mother-in-law or boss to prove that there is something besides air and spinal fluid between your ears?)
- Neuroimaging kiosks in the malls and airports: "Get-a-scan-while-you-wait"
- A collage of color brain maps of the whole family (good for Christmas cards or the grandparents' scrapbook)
- A copy of your latest BEAM study to show your significant other (notice the maximal activity in the limbic system)

High-tech "hardware" advances in pediatric neurology have paralleled or even exceeded those in other aspects of medicine. I rejoice at the beautiful "windows to the brain" we now have available in the form of modern CT head scanning and MRI imaging. I will never miss subjecting infants and young children to the painful and potentially hazardous neurodiagnostic procedures of the 1960s.

But things have gotten out of hand. We all recognize the importance and necessity of paying the bills in office practice. The new array of neurodiagnostic tests is seductive. Who wouldn't like to "see" inside the young child's brain with a full-color "brain map"? However, too much emphasis is being placed on neurological marketing to generate income from such studies. In reality, the clinical indications for their use are relatively few.

Pediatricians should keep these developments in mind as they choose neurologic consultants. The costs of care for children with neurological disorders are heavily determined by the use of neurodiagnostic procedures. As long as some neurologists continue to generate significant portions of their income from the performance of these procedures, built-in conflicts of interest are inescapable. The modern child neurologist can be of most help to his or her pediatrician-colleagues by serving as a consultant—doing a history, performing a careful neurological examination, and recommending *pertinent* ancillary diagnostic tests, when clinically indicated.

Informed Consent for Lumbar Puncture

Jeffrey R. Botkin, MD, MPH

• Informed consent procedures are commonly employed prior to lumbar puncture. An understanding of the legal and ethical basis of informed consent is important in developing an acceptable approach to consent and in dealing with problems confronted when consent cannot be obtained. I review the current legal concepts in informed consent and their ethical foundation, and make recommendations to clinicians for obtaining consent for this common procedure in the ambulatory pediatric population.

(AJDC. 1989;143:899-904)

Despite the frequent use of consent procedures, many physicians remain uncertain about the legal and ethical requirements of informed consent. There is a growing literature on the theory and practice of informed consent,^{1,4} but there has been relatively little published in the medical literature that provides specific guidance to the clinician.

For editorial comment see p 885.

Unfortunately, the law and ethical theory are crude instruments for the guidance of physicians in their daily care of patients. As a result, there is inconsistency in our practice with respect to informed consent; we generally obtain consent for some procedures, such as lumbar puncture, while others, such as arterial puncture for blood gas measurement, are generally performed without consent. An understanding of the developing legal and ethical basis for informed consent will provide a rational foundation for consent practices and may foster a more consistent approach

based on a morally acceptable standard of care.

Lumbar puncture serves as an appropriate focus for this review since it is a common procedure performed in pediatric practice for which informed consent is usually obtained from the child's parent or guardian. Following a review of the legal and ethical aspects of informed consent, I will offer general recommendations for appropriate informed consent for lumbar puncture in the ambulatory pediatric population. Hypothetical cases will be presented to illustrate the issues, and the implication of these recommendations for other common procedures will be discussed.

THE ETHICAL BASIS OF INFORMED CONSENT

The philosophical and legal basis for informed consent was expressed in 1914 by Justice Cardozo: "Every human being of adult years and sound mind has a right to determine what shall be done with his own body."⁵ This right is rooted in the ethical principle of autonomy or self-determination. Ideally, informed consent is the process by which competent patients maintain informed control over their medical care.

The appropriate expression of patient autonomy in the contemporary patient-physician relationship remains a topic of debate; however, it is clear that there has been a significant transfer of control from the physician to the patient over the last century. The 1847 American Medical Association Code of Ethics stated: "The obedience of a patient to the prescriptions of his physician should be prompt and implicit. He should never permit his own crude opinions as to their fitness, to influence his attention to them."⁶ The expansion of choices in medicine over the century and the decline in unquestioned authority in our society have led to the conclusion that the patient's opinions, crude or other-

wise, are essential to defining the best course for individual welfare. The right of the patient to make informed choices on issues affecting health is now a fundamental component of the patient-physician relationship. To a large extent, this change in the clinical relationship with respect to informed consent has been driven by changes in legal standards.

LEGAL STANDARDS FOR INFORMED CONSENT

In general terms, the current legal standard requires the physician to disclose to the patient the diagnosis, the prognosis with and without treatment, and the alternatives for treatment with their attendant risks and benefits. While this standard will apply in the great majority of clinical circumstances, there are four recognized exceptions to the requirement for informed consent: (1) medical emergencies, (2) incompetent patients, (3) patient's expressed waiver of consent, and (4) therapeutic privilege.² A brief discussion of each of these exceptions is appropriate.

Informed consent is frequently deferred in medical emergencies. Urgent situations require decisive action and there is no time for a consent process. "Presumed consent" is invoked in emergencies with the assumption that most people would consent to reasonable attempts to save life or limb. Explicit refusals of care may also not be honored in emergency situations because the competency of the patient may not be ascertainable—the person who attempts suicide being an obvious example.

Waiver of consent applies to those situations when the patient *explicitly* transfers decision-making authority to the physician. Acceptance of a waiver is most appropriate *after* the full disclosure of relevant information. Physicians need not force patients to make decisions when patients are psychologically unprepared to do so. However, physi-

Reprints not available.

cians should be reluctant to accept decision-making authority when the decisions are highly value laden.

The problem of the incompetent patient raises a number of complex issues. Strictly speaking, *competency* is a legal term, and in some circumstances the physician must turn to the courts for the determination of the patient's competency. In practice, physicians make implicit or explicit determinations of competency on a daily basis. If a patient is deemed incompetent, informed consent is generally obtained from the next of kin or the legal guardian. Thus, informed consent, albeit from surrogates, remains an integral part of the care of the patient. It is clear, however, that competency (in the nonlegal sense) is not an all-or-none phenomenon. Patients may be competent to understand basic choices with less than life-threatening consequences but unable to adequately comprehend complex choices with potentially grave consequences. Patients should retain control over that portion of their health care they fully understand.

Therapeutic privilege refers to the physician's prerogative of withholding information that he or she believes may be harmful to the patient. In a coronary care unit, for example, the medical staff may choose to withhold information from a competent patient about his or her condition and the therapeutic options while the patient is in a clinically unstable condition. Therapeutic privilege is a controversial exception, and the law remains unclear about the extent of this privilege.⁶ Therapeutic privilege should never be employed to override a competent patient's expressed wishes. Many commentators argue that therapeutic privilege should only be invoked if the anticipated harm to the patient is likely to be immediate and severe.

LEGAL THEORY

Two important transitions in the doctrine of informed consent have occurred over the past several decades. While consent per se has been a legal requirement for medical care at least since Justice Cardozo's influential opinion in 1914, the birth of *informed* consent dates to 1957. In the case of *Salgo v Leland Stanford Jr University Board of*

Trustees, the court established the physician's duty to disclose "any facts which are necessary to form the basis of and intelligent consent by the patient to the proposed treatment."⁷ Thus, for consent to be considered valid, the patient must be given sufficient information to understand the nature of the decision, although, as will be discussed, the definition of "sufficient information" remains unclear.

The second important transition involves the legal theory underlying informed consent. Many of the early informed consent cases were decided on the basis of the legal theory of battery. Battery is defined as the unconsenting "touching" of one individual by another. Under this legal theory, no harm needs to result from the touching—the physician would be liable if a procedure was performed for which consent had not been obtained, even if the patient experienced no harm from the procedure. In recent decades, the legal basis has shifted to a negligence theory, that is, malpractice. Under a negligence theory, a successful suit will be dependant on the plaintiff's ability to demonstrate five key elements in an informed consent case: (1) the physician must owe a duty to the patient to provide information, (2) breach of the duty must be demonstrated, (3) the patient must suffer harm, (4) the harm must represent the development of an undisclosed risk, and (5) had the patient been informed of the risk, he or she would not have consented to the procedure.⁸

Of particular importance to our discussion is the requirement that the patient be able to plausibly argue that he or she (or any reasonable person) would have refused the procedure if he or she had been informed of the risk. The corollary of this is the requirement for physicians to provide all the information that a reasonable person would require to make a decision. This has been termed the "reasonable person" standard of disclosure. (Some state jurisdictions require only that a physician provide the same information that other physicians provide to patients in similar circumstances. This is often a less stringent standard than the reasonable person standard.) Of course, it may be difficult for a physician or a jury to decide what level of risk a reasonable person would

require in a given clinical circumstance. It is clear, however, that the physician need not deliver a "polysyllabic discourse on all possible complications."⁹ There are no clear rules for physicians to follow in this respect; disclosure is guided by the facts of the individual case. It is fair to assume, however, that reasonable people would not forgo life-sustaining treatments due to remote risks of harm. Conversely, reasonable people might well forgo elective procedures due to risks of a small magnitude.

CONSENT FORMS

In the typical clinical context, the law does not require the signing of consent forms by patients.¹⁰ It is patient understanding and active participation in decision making that is significant to the law and ethics of informed consent. Consent forms have two principal values: (1) They can foster patient education with respect to the proposed treatment or procedure. To promote this goal, consent forms must be clearly and simply written using lay terms and should be customized for the proposed procedure or treatment.^{11,12} Education for more complicated treatments or procedures may be best handled in written form. (2) Signed consent forms may provide some legal protection for physicians if the forms are used as documentation that an informed consent process has occurred. A signed form itself, however, provides no protection if the patient can plausibly claim that the diagnosis and the risks of, benefits of, and alternatives to the procedure were not adequately discussed prior to the signature and/or the signature was obtained without an opportunity to read and understand the form.¹³ Patient understanding and participation can be documented by a signature, but the clinical reality is that signatures can be obtained easily from many patients with little or no discussion of the relevant information.¹⁴ A court of law may view the signature accordingly. Clear documentation in the physician's records noting a discussion of consent is adequate in lieu of a consent form from a legal and ethical perspective. (Hospital or department regulations may require consent forms, as do institutional review boards in research settings.) True informed

consent is the physician's best legal defense with or without a signed consent form.

INFORMED CONSENT FOR CHILDREN

The informed consent process in the pediatric population has important differences from the process with competent adults. Young children are not competent to consent to treatment or procedures. (The competency of older adolescents is a complex issue from both the legal and ethical perspectives and will not be addressed in this discussion.¹⁵) It is the responsibility of parents or guardians to provide informed consent for children. The discretion of parents is limited, however. Competent adult patients clearly have the legal and moral right to refuse any or all treatments for any reason they deem sufficient—even life-sustaining procedures. Parents, however, do not have the same absolute right to refuse treatment or procedures on behalf of their children.¹⁶ For example, parents have not been permitted by the courts to refuse chemotherapy for a child with leukemia,¹⁷ to refuse removal of an optic glioma,¹⁸ or to refuse blood transfusion when the child's life is in imminent danger.¹⁹ Conversely, courts have refused to rule against the wishes of parents when the child's medical condition is not serious or life threatening.²⁰⁻²² The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research²³ and the Committee on Bioethics of the American Academy of Pediatrics²⁴ have supported limitations on parental authority when the health of a child is in jeopardy. These precedents suggest that parental discretion is broad but that it does not include choices that may seriously threaten the welfare of the child.

LUMBAR PUNCTURE

With this background we can look more specifically at the issue of informed consent for lumbar puncture in the ambulatory pediatric population. These comments will pertain to lumbar puncture as a diagnostic procedure for suspected intracranial infection and do not pertain to lumbar puncture as a therapeutic measure. Also, the risks and benefits of lumbar puncture in sick

neonates is more complex than in the ambulatory population and will not be dealt with here.

Lumbar puncture is principally used for the diagnosis of meningitis, and it must first be noted that there are no appropriate alternatives to the lumbar puncture for establishing this diagnosis. The advantages of making a rapid diagnosis are obvious: treatment can be initiated, pathogens can be identified and sensitivities established, complications and sequelae of the illness can be anticipated, and appropriate public health measures can be instituted when indicated. Bacterial meningitis remains a life-threatening illness despite antimicrobial therapy, with a mortality in neonates of between 15% and 20%.²⁵ Mortality beyond the neonatal period is less than 10%; however, neurologic sequelae may be present in as many as 50% of the survivors, including hearing deficits, seizures, motor impairments, and learning and developmental disabilities.²⁶ Delay in the diagnosis of meningitis is a recognized risk factor for disease sequelae.²⁶ The benefits of lumbar puncture are clear: it is an essential procedure for the diagnosis of a serious and potentially life-threatening illness.

Unfortunately, data do not exist to accurately assess the risks of lumbar puncture in the pediatric population. The adverse reactions listed by Klein et al²⁵ include pain from the procedure itself, headache, bleeding into the tissues surrounding the spinal column or into the cerebrospinal fluid, and herniation of the temporal lobes through the tentorium or herniation of the cerebellar tonsils through the foramen magnum. Other reported risks include local infection, transient or persistent paresthesias or leg numbness, cranial nerve palsies, and seeding of the meninges in bacteremic patients.²⁷ The subjective nature of some of these complications will make them impossible to quantify in the young population. Marton and Gean²⁷ have provided a recent review of the literature on lumbar puncture with data principally from the adult population. The reported incidence of headache is quite variable, depending on the technique and position used, but is generally believed to be in the 10% to 25% range. In those receiving spinal anesthesia, 13% had immediate painful par-

asthesias, 0.2% had persistent paresthesias, and 0.7% had leg numbness that disappeared within 1 year. Transient cranial nerve palsies were reported in 0.02% of patients.

"Traumatic taps" are frustratingly frequent; Morton and Gean²⁷ report an incidence of 20%. The vast majority of these are of no clinical significance other than the difficulty created in interpreting the cerebrospinal fluid results. However, spinal subdural or epidural hematomas can develop in those patients with coagulation disorders and these can produce serious sequelae. Ruff and Dougherty²⁸ reported an incidence of major complications of 6.7% in 342 patients given anticoagulants after lumbar puncture, including 1.5% who developed paraparesis. A traumatic tap increased the risk of a major complication in this group. The risk of a symptomatic hematoma in the pediatric population without known coagulation disorders is unknown, but based on the above data the incidence of serious sequelae must be exceedingly small.

A potential risk of inducing meningitis by lumbar puncture in the bacteremic child was identified by Teele et al.²⁹ However, that study did not control for other clinical variables, and it is possible that the association between lumbar puncture and subsequent meningitis was an artifact produced by the selection of the sickest patients for lumbar puncture. Shapiro et al³⁰ evaluated this issue in 310 children with occult bacteremia in a study that controlled for a number of variables. Their results led them to conclude that the risk of meningitis from lumbar puncture in bacteremic patients was insignificant and was outweighed by the information obtained from the procedure.

The most serious complication of lumbar puncture is herniation. This complication may be fatal even with prompt recognition and treatment. Dodge and Swartz³¹ diagnosed herniation in 10 of 29 patients dying of acute bacterial meningitis. The overall incidence of herniation in their adult and pediatric cases of bacterial meningitis was 5.1%. One case of herniation occurred prior to lumbar puncture, 3 occurred within 2 hours of the procedure, and 5 occurred more than 2 hours later.

In the largest reported pediatric se-

ries to date, Horowitz et al³² found an incidence of herniation of 6% in 302 infants and children admitted to a tertiary care center for acute bacterial meningitis. In this series, 1 patient developed herniation immediately following lumbar puncture and another 7 of 18 patients with herniation developed their symptoms within half an hour of admission. This study was performed by reviewing charts retrospectively for cases over a 9-year period, so the quality of the data may be limited.

The review of the literature on lumbar puncture by Marton and Gean²⁷ suggests that the incidence of herniation in adult patients with evidence of raised intracranial pressure is in the general range of 1%.

Due to the risk of herniation, however, it is generally recommended that lumbar puncture be withheld pending further evaluation in those patients who exhibit indications of raised intracranial pressure. These indications include altered level of consciousness, a history of significant head trauma, Cushing's triad, papilledema, focal neurologic signs, neurologic signs preceding the acute illness such as progressive headache or persistent vomiting, or an abnormal computed tomographic scan.^{25,33,34} In their pediatric series, Horowitz et al³² were unable to identify clinical criteria on a patient's admission to the hospital that would have predicted herniation.

The difficulty with these data is that they do not permit an assessment of the cause-and-effect relationship between lumbar puncture and herniation. Herniation is a well-recognized complication of the primary disease process in meningitis. Without a controlled prospective study, it is impossible to determine what proportion of patients with herniation would have developed it without the procedure. In addition, our estimation of risk for consent purposes must be based on all children undergoing lumbar puncture, which is a much larger number than those subsequently diagnosed with bacterial meningitis.

Based on this limited information, we can conclude that the risk of herniation attributable to lumbar puncture is unknown, but is probably quite small in the ambulatory pediatric population for which the procedure is indicated.

In summary, the lumbar puncture is a

safe procedure for which there are no acceptable alternatives for the diagnosis of life-threatening intracranial infections. These features of the illness and the procedure will guide the informed consent process and will place some limitations on a parent's ability to refuse the procedure.

RECOMMENDATIONS FOR INFORMED CONSENT

These recommendations are intended to provide general guidance to physicians based on the legal and ethical considerations cited above. To my knowledge, there have been no legal cases that address the physician's specific obligations in this particular clinical circumstance. These recommendations are therefore based on analogy and precedent, which are fundamental to legal decision making but provide no guarantees for future rulings. Each legal case is always considered in light of the particular facts involved.

When a lumbar puncture is clinically indicated for suspected meningitis, the parents should be fully informed by the physician about the child's clinical condition and the concern about meningitis. Meningitis should be explained in lay terms, and parents should be aware that it is a serious condition. Specific details of morbidity and mortality from meningitis need not be presented prior to the definitive diagnosis, although parents' questions should be answered in full. The need for a lumbar puncture, the nature of the procedure, and the lack of available alternatives should be discussed. Parents are often alarmed by the description of the lumbar puncture, but the physician can reassure parents about the safety of the procedure. Common complications, such as local pain and headache, should be discussed. Parents should be informed that serious complications of the procedure are rare and that the greatest risk to the child lies with an undiagnosed meningitis. The specific nature of the remote risks need not be discussed unless the parents ask. In legal terminology, these remote risks should not be "material" to a reasonable person's decision to consent to the procedure in these clinical circumstances.

Signing of a consent form by the parents is not necessary if the above discus-

sion has taken place and is briefly documented in the progress chart. If the use of a form is preferred, it should be designed to relate information specific to lumbar puncture in language comprehensible to the individual signing the form. Parents must be given the opportunity to read the form and ask questions about its content. It should be emphasized again that the consent form will not provide the physician with legal protection if the parents can plausibly claim that they did not know what they were signing.

Two hypothetical patient histories follow that represent problems in obtaining consent and illustrate some of the legal and ethical dimensions discussed.

1. Alisa is a 20-month-old previously healthy female infant who presents to a pediatrician with a 4-day history of rhinorrhea and a 2-day history of fever and irritability. The child is febrile and appears lethargic but responsive. Her physical examination is notable for nuchal rigidity. There is no other focus of infection apparent on physical examination; no focal neurologic signs are apparent and there is no papilledema. Alisa is accompanied by a foster parent who has temporary custody of the child. The foster parent has not been given a release for medical treatment and the social worker assigned to the case is unavailable. Should the physician obtain court authorization before proceeding with the lumbar puncture?

2. The same child presents to the physician's office in the same physical condition, but she is now accompanied by her parents who have legal custody. After a full discussion of the child's condition, the parents refuse consent for lumbar puncture.

In the first scenario, a problem arose with consent because there was no appropriate decision-making authority available for the child. In this circumstance, if the parents can be contacted without delay, this is certainly the appropriate next step. If the parents are unavailable, the time necessary to obtain an authorization from court would jeopardize the welfare of the child. The physician should proceed with lumbar puncture and appropriate care for the child, and court approval can be pursued later if necessary. The physician will not

be liable for malpractice for lack of consent if he or she has used good clinical judgment, even if harm subsequently develops from the care rendered.

The second scenario is a problem of parental refusal of lumbar puncture despite clear medical indications. In this circumstance, additional discussion with the parents is warranted. An exploration of the parent's beliefs may uncover misconceptions about the potential serious nature of the child's condition, the motivation of the physician, or the risks of the procedure. A second opinion by a colleague may help allay the parent's unjustified fears. If the parents continue to refuse the procedure, the physician's primary obligation is to the welfare of the child. Unless a court order can be obtained promptly, lumbar puncture and treatment should proceed without consent, and court approval can be sought for continued care if necessary.

When meningitis is suspected, the parents' discretion to accept or reject diagnosis and treatment is limited. A successful negligence suit based on lack of informed consent would require that the child suffer a net harm from the procedure and parents would have to claim that reasonable people would not have consented to the procedure under the given circumstances. If the physician has exercised good clinical judgment, this should not be a plausible claim. In general, a physician taking urgent action with skill and good conscience for the significant welfare of a child is unlikely to be the victim of a successful malpractice suit for lack of consent. Failure to provide appropriate care for a child due to misguided fears of legal liability is the greater moral and legal transgression.

These principles should also hold true for those clinical circumstances when meningitis is less likely than in the scenarios presented. The child who is febrile without an apparent cause on examination is the most common candidate for lumbar puncture, and, of course, the great majority of taps are negative. Nevertheless, if the physician has used reasonable clinical judgment in the determination that a lumbar puncture is indicated, there should be no legal repercussions if the procedure is performed without consent, even if harm develops from the procedure (if competently performed).

IMPLICATIONS FOR OTHER PROCEDURES

With respect to informed consent, it is my opinion that lumbar puncture constitutes a "paradigm case," in which the resolution of the legal and ethical issues is clear and, as such, the case can serve as a model for decision making in other clinical circumstances. If another procedure is similar to lumbar puncture in all relevant ways, then the standards of consent for the procedure will also be similar. Conversely, if a procedure differs in relevant ways from lumbar puncture, the differences can be analyzed with respect to the legal and ethical principles of informed consent, and a different standard of consent can be utilized accordingly. Understanding the technical, legal, and ethical foundations of a paradigm case thereby assists in guiding consent for a variety of clinical circumstances.

The features of the lumbar puncture that make it a paradigm case are the lack of reasonable alternatives, the emergent nature of the procedure, and the

high benefit-to-risk ratio, including the potential benefit of the preservation of life. In general, all of these features would need to be present for a physician to override the parents' refusal of the procedure or treatment without legal authorization. Other procedures performed by pediatricians that would probably meet these criteria, depending on the clinical circumstance, would include a paracentesis for suspected peritonitis and a thoracentesis for pneumonia with effusion and respiratory failure. A myringotomy in a patient with mastoiditis or a bladder tap in a febrile infant would not meet the above criteria due to the alternatives and/or the less serious nature of the conditions. The risks disclosed should always be guided by what a reasonable person would require to reach a decision in the situation at hand, which will depend on the potential benefits of the procedure as well as the nature and the magnitude of the specific risks involved. No specific guidelines can replace the physician's good judgment in this respect.

The lack of complete parental authority in emergent situations should not be taken as a liberty to give perfunctory attention to informed consent. The advantages of informed consent extend beyond its legal bounds. Informed parents who are active participants in care decisions will have greater trust in the physician and a better appreciation of the strengths and limitations of modern medicine. A relationship of mutual respect between parents and physicians will ultimately benefit parents, physicians, and children.

I thank Rebecca Dresser, JD, and Robert Eiben, MD, for their comments in the preparation of the manuscript.

Book Review

Peace of Mind During Pregnancy, by Christine Kelley-Buchanan, 384 pp, \$24.95, New York, NY, Facts on File Publications, 1988.

Between 40% and 90% of all women in the Western world use at least one medication during pregnancy. Since the thalidomide tragedy, every drug has been viewed as a potential teratogen. In fact, only roughly 20 xenobiotics are proved human teratogens. In a recent study conducted in Toronto, Canada, we showed that women consulting the Motherisk program (an antenatal consultation service for drug, chemical, and radiation exposures) assign themselves a 25% teratogenic risk when exposed to nonteratogenic drugs.

Clearly, there is a need for authoritative information on the risk of exposure to drugs, chemicals, radiation, or infection in pregnancy. Although it is facile to say, "Do not use during pregnancy," more than 50% of the women contacting the Motherisk program do so after realizing that conception occurred while being exposed to the agent in question. For these women, the notion "do not use during pregnancy" may easily translate to "terminate pregnancy if you have been exposed." It is equally important that the expectant mother and her family not only understand available information, but comprehend the limitations in the type of epidemiologic research that leads to current recommendations.

Ms Kelley-Buchanan's book deals very well with these issues. The title is somewhat misleading, seeming to address laypeople but risking dismissal by the medical professional as "too simplistic." Not so. This is a very professional book, more so than most available A through

Z teratology handbooks that do not weigh data, but simply quote them. The book is written by a genetic counselor who obviously has weighed the safety/risk ratios of environmental agents and has integrated and explained this information on a daily basis. Most teratology texts lack this practical clinical approach.

The text not only is excellent in its approach but is scientifically sound. Relevant, current data are presented, and methodological weaknesses are exposed. For example, most scientific literature on lithium teratogenicity is based on the Danish lithium registry. Pertinent methodologic flaws in the registry data collection and the background incidence of these malformations in the general population are discussed. No other current teratology handbook includes this important information.

Because of the thorough, analytic discussion, the book reviews only 200 agents. It does not profess to be a comprehensive compendium of all environmental exposures in pregnancy. Instead, all known and suspect human teratogens are included as well as the common drugs likely to be used by women of childbearing age. This book has the rare potential of becoming an important reference for both laypeople and health professionals alike.

Perinatal Outcome of Infants Exposed to Cocaine and/or Heroin In Utero

Richard Fulroth, MD; Barry Phillips, MD; David J. Durand, MD

• While cocaine is now used much more frequently than heroin by women of childbearing age, we have found that a significant number of mothers have abused both drugs during their pregnancy. We studied 86 infants who were born to women with a history of cocaine and/or heroin use during pregnancy. The newborns were observed over a 5-day hospital period using a standardized abstinence scoring system and urine drug screening of both mother and infant. Of these, 35 had maternal and/or newborn urine test results that were positive for cocaine only (cocaine group), 14 that were positive for heroin only (heroin group), 17 that were positive for both cocaine and heroin (cocaine/heroin group), and 20 that were negative for both, although the mothers admitted to cocaine use during their pregnancy (cocaine history group). In approximately half of the mother/infant pairs, the

results of the urine drug tests were discordant. Microcephaly and growth retardation occurred most frequently in the infants in the cocaine group (17% and 27%, respectively). Microcephaly was also found to be significant in the infants in the cocaine/heroin group. Signs of drug withdrawal occurred in all four drug-exposed groups. Mild withdrawal occurred in 26% of infants in the cocaine group, 21% of the infants in the heroin group, 47% of the infants in the cocaine/heroin group, and in 30% of the infants in the cocaine history group. Withdrawal requiring treatment occurred in 6% of the infants in the cocaine group, 14% of the infants in the heroin group, 35% of infants in the cocaine/heroin group, and 5% of the infants in the cocaine history group. The use of heroin with cocaine has a synergistic effect on the behavior of the newborn.

(AJDC. 1989;143:905-910)

Both cocaine and heroin are used with alarming frequency by women of childbearing age. Although the majority of the infants that we now see with prenatal exposure to illicit drugs are born to mothers who are cocaine abusers, almost one fourth of them are born to mothers who are abusers of both cocaine and opiates. While there is a substantial amount of information available about the effects of prenatal exposure to heroin, less is known about the effects of prenatal exposure to cocaine. Virtually nothing is published about the effects of prenatal exposure to combined cocaine and opiates. It was to characterize infants born to mothers who used both cocaine and opiates during their preg-

nancy that we undertook this study.

The effects of cocaine on growth and behavior have recently been described.¹⁻³ Madden et al⁴ described eight newborns with positive urine test results for cocaine who did not show signs of withdrawal; their study was performed without a standardized abstinence scoring system. Bingol et al⁵ found significantly decreased birth weight and head circumference in a group of 160 infants whose mothers used cocaine during their pregnancy. Chasnoff et al⁶ found no difference between the birth weight and head circumference of 23 infants born to mothers who used cocaine during pregnancy and those born to a control group. They did find an increased incidence of tremors and interactive behavioral abnormalities in the infants born to mothers who used cocaine, although they did not report withdrawal requiring treatment. Naeye et al⁷ found that infants exposed to heroin frequently are growth retarded, show meconium staining, and

are premature. The frequency and severity of heroin withdrawal has been compared with that of methadone hydrochloride and has been found to be just as frequent but less severe.⁷ Ryan et al⁸ found that infants exposed to both cocaine and methadone had the same frequency of abstinence scores as a group of infants exposed to methadone only. Oro and Dixon⁹ reported that infants exposed to cocaine and narcotics have the highest morbidity compared with infants exposed to cocaine or narcotics alone.

We undertook this prospective study of newborns who had been prenatally exposed to cocaine and/or heroin to determine if urine drug screening should be extended to both mother and infant to improve detection, to examine the relative impact of these drugs on fetal growth, abnormal behavior, or withdrawal, as well as to determine whether infants exposed to both drugs showed any signs of synergistic effects.

PATIENTS AND METHODS Study Population

We collected data on all infants who were delivered at Highland General Hospital, Oakland, Calif, during a 28-week period. During the study period there were 1129 infants born alive. We initially identified 108 newborns as study candidates by either a history of maternal drug abuse or a suspicion of maternal drug abuse. The remaining 1021 infants, including 985 who were born at term and 36 who were born prematurely, were thought to be drug free. Seventeen newborns who were initially identified because of suspected maternal drug abuse were subsequently excluded because their mothers denied the use of cocaine and heroin, and both maternal and newborn urine tests were negative for cocaine and heroin. An additional 5 newborns were excluded when maternal urine screens were inadvertently not obtained. The remaining 86 newborn/mother pairs with documented exposure to

Accepted for publication August 1, 1988.

Table 1. — Results of Urine Drug Tests on 86 Mother/Newborn Pairs in the Study Population*

Drugs Detected in Urine	Drug Group			Cocaine History (n = 20)
	Cocaine (n = 35)	Heroin (n = 14)	Cocaine/Heroin (n = 17)	
Cocaine	35	0	17	0
Heroin	0	14	17	0
Methadone	0	1	0	0
Methamphetamine	2	3	3	1
Tetrahydrocannabinol	7	1	3	2
Alcohol	0	1	0	0

*Values represent the number of pairs where the urine of the mother and/or her newborn contained the specified drug.

cocaine and/or heroin are included in this report.

All women who delivered infants during the 28-week period were questioned about drug abuse during the pregnancy by an attending obstetrician at the time of admission, by an attending pediatrician (R.F.) at the time of the infant's birth, and by a social worker before discharge. Study newborns were defined as those who met one of the following criteria: (1) infants born to mothers who admitted the use of any illicit drugs during pregnancy; (2) infants born to mothers who gave a negative history of illicit drug use, but with such signs of drug abuse as needle track marks or withdrawal symptoms; or (3) infants who showed signs that were compatible with neonatal withdrawal.

Study newborns were compared with infants with no history of drug exposure during pregnancy. Our study was approved by our hospital institutional review board for studies involving human subjects.

Study Protocol

We estimated the gestational age of the newborns by the modification by Ballard et al¹⁰ of the Dubowitz method. We calculated the mean and SD for birth weight and head circumference of the infants born at term without a history of drug exposure who were delivered during the study period. We defined growth retardation as a birth weight that was more than 2 SDs below the mean of these infants. Similarly, we defined microcephaly as a head circumference more than 2 SDs below the mean.

All study newborns were admitted to the nursery where they were observed and treated according to our standard protocol for infants at risk for withdrawal. They were observed for a minimum of 5 days, during which time they were scored for signs of drug withdrawal. Urine samples were obtained from the mother at the time of her admission to the hospital and from the newborn at first void in the nursery for drug screening. Maternal urine samples required 50 mL, and the

infant urine sample required 10 mL, which was collected in all cases. None of the women received morphine or other opiate medication while in the hospital and before the delivery of their newborn or before the time the urine samples were obtained.

The urine samples from the infants and their mothers were tested for the presence of cocaine, heroin, methadone, methamphetamine, tetrahydrocannabinol, and alcohol. The drugs were identified by thin-layer chromatography, including a step to convert bound morphine to free morphine. Heroin was identified as urinary morphine. Results were confirmed by enzyme immunoassay. Sensitivity is 1 mg/L of urine for the thin layer chromatography procedure and 0.3 mg/L (95% confidence interval) for the enzyme immunoassay for both cocaine and heroin. The results of the urine tests were not known by the nurses who performed the abstinence scoring.

Abstinence Scoring

We assessed drug withdrawal by the abstinence scoring system reported by Finnegan,¹¹ which measures 21 signs of drug withdrawal, including increased tone, tremulousness, tachypnea, decreased sleep time, and feeding disturbances. The study newborns underwent scoring every 4 hours, except when scores exceeded 12, which suggested moderate or severe withdrawal. In these cases, they underwent scoring every 2 hours.

All newborns with a score greater than 12 recorded three times in succession (with scoring done every 2 hours) were examined by a second scorer to ensure that they had unequivocal signs of moderate to severe withdrawal. They were then treated for withdrawal.

Abstinence scores were also assigned to a group of 29 control infants who were born by cesarean section during the study period to mothers without a history of drug use. These newborns were used to demonstrate the validity of the scoring system. Newborns who

were delivered by cesarean section were chosen as a control group because they were expected to remain in the nursery for 5 days. All scorers underwent a course of instruction before the beginning of the study to standardize the evaluation of abstinence symptoms.

Treatment

The decision to treat all newborns who had a score above 12 was reached after a 4-month trial period before our study in which the clinical assessment of withdrawal by the attending pediatrician (R.F.) was compared with abstinence scores. Newborns suffering from withdrawal were treated with phenobarbital sodium,¹² so that blood levels could be monitored. All newborns had a complete blood cell count, and serum calcium, magnesium, and glucose levels were obtained before treatment to rule out other causes of signs of withdrawal.

Statistical Analysis

We compared groups with a Fisher Exact Test. $P < .05$ was considered significant. All data are represented as mean (\pm SD).

RESULTS

The 86 newborn/mother pairs were placed in one of four groups. Table 1 lists the results of the urine drug tests of the infants in these four groups. The first group (cocaine group) consisted of 35 newborns in whom the urine screen results of either the mother and/or the newborn were positive for cocaine but negative for heroin. The second group (heroin group) consisted of 14 newborns in whom the maternal and/or newborn urine screen results were positive for heroin but negative for cocaine. The third group (cocaine/heroin group) consisted of 17 newborns with maternal and/or newborn urine screen results positive for both cocaine and heroin. The fourth group (cocaine history group) consisted of 20 newborns whose mothers admitted to cocaine use at some time during their pregnancy, but for whom both the maternal and newborn urine screen results were negative for cocaine and heroin. These four groups were compared with the 1021 infants born to mothers without a history of drug use during pregnancy (no drugs group).

The results of many of the maternal and newborn urine screens were discordant for both cocaine and heroin (Table 2). In only 50% of the cases where maternal and/or infant test results for co-

Table 2.—Urine Drug Test Results Showing the Frequency of Discordant Results for the Mother and Her Infant*

Group	Drug Group

caine were positive were both the maternal and infant urine test results positive. Similarly, only 42% of the maternal/infant pairs who had positive test results for heroin had positive test results for both the maternal and infant urine.

Abstinence Scores

Table 3 shows the eight most common signs and symptoms recorded in each of the drug groups. Tremors and hypertonicity were found most frequently; the other signs and symptoms are recorded in decreasing order of frequency.

Figure 1 shows the distribution of abstinence scores in each group of newborns. A score of less than 9 was interpreted as normal and a score between 9 and 12 was interpreted as mild withdrawal. A score greater than 12 was interpreted as moderate to severe withdrawal. Infants with a score greater than 12 were treated for drug withdrawal. Twenty-four (69%) of the 35 newborns in the cocaine group, 9 (64%) of the 14 newborns in the heroin group,

3 (18%) of the 17 newborns in the cocaine/heroin group, and 13 (65%) of the 20 newborns in the cocaine history group had scores less than 9. All 29 newborns in the cesarean section group had scores less than 9. Scores between 9 and 12 occurred in 9 of the newborns in the cocaine group (26%; $P < .005$, compared with the cesarean section control group), 3 infants in the heroin group (21%; $P < .05$, compared with the cesarean group), 8 infants in the cocaine/heroin group (47%; $P < .0001$, compared with the cesarean group), and in 6 infants in the cocaine history group (30%; $P < .005$, compared with the cesarean group).

Table 4 shows the number of infants treated with phenobarbital for each of the drug groups. One infant in the cocaine group had a seizure and was treated with phenobarbital before reaching an abstinence score of 13. No infant in any of the other groups had a seizure. Six infants in the cocaine/heroin group (35%; $P < .01$, compared with the cesarean group) had scores above 12

and were treated for withdrawal for an average of 21 days (range, 13 to 33 days).

Growth Retardation

Figure 2 shows the percentage of infants born at term in each group who were growth retarded based on the mean (\pm SD) weight of the 985 infants born at term in the no drugs group. Five (17%) of the 30 newborns born at term in the cocaine group (birth weight, 2820 ± 356 g), 1 infant (8%) of the 12 in the heroin group (3167 ± 646 g), 1 infant (7%) of the 15 in the cocaine/heroin group (2999 ± 354 g), and 1 infant (5%) of the 20 in the cocaine history group (3118 ± 474 g) had growth retardation. Twelve (1%) of the 985 newborns born at term without a history of drug exposure (3351 ± 469 g) had growth retardation. The difference between the incidence of growth retardation in the cocaine group and the no drugs control group was highly significant ($P < .0001$). The difference in the incidence of growth retardation among the other three groups and the no drugs control group was not significant.

Microcephaly

Figure 2 shows the percentage of newborns born at term in each group who were microcephalic based on the mean (\pm SD) head circumference of the 985 infants born at term in the no drugs group. Eight (27%) of the 30 newborns born at term in the cocaine group (head circumference, 32.3 ± 1.5 cm), 2 (17%) of the 12 infants in the heroin group (33.2 ± 1.8 cm), 3 (20%) of the 15 infants in the cocaine/heroin group (32.6 ± 1.3 cm), and none of the 20 infants in the cocaine history group (33.8 ± 1.2 cm) were microcephalic. Thirty-six (4%) of the 985 newborns born at term in the no drugs group (34.0 ± 1.5 cm) were microcephalic. The incidence of microcephaly was significantly higher in the cocaine group ($P < 10^{-4}$) and in the cocaine/heroin group ($P < .02$) than in the no drugs group.

Clinical Outcome

There were no significant differences between the 86 newborns in the study and the 1021 no drugs controls for any of the following characteristics: age, sex, race, 5-minute Apgar scores of less than

Fig 1.—Abstinence scores for infant groups as assessed by the Finnegan method.¹¹ Scores of less than 9 are defined as no withdrawal, 9 to 12 as mild withdrawal, and more than 12 as moderate or severe withdrawal. Asterisk indicates $P < .05$, when compared with the cesarean section control group by a Fisher Exact Test.

Table 4.—Percent of Infants Who Were Treated for Signs of Withdrawal, and the Mean Duration of Treatment

	Drug Group			
	Cocaine (n=35)	Heroin (n=14)	Cocaine/Heroin (n=17)	Cocaine History (n=20)
Treated, %	6	14	35	5
Duration of treatment, d	2	14	21	18

7, sepsis, congenital malformations, and need for transfer to a tertiary care nursery.

Maternal smoking occurred in 9 (82%) of 11 of infants in the cocaine group who were small for gestational age. All infants who were small for gestational age in the other three groups had mothers who smoked cigarettes. Five (14%) of the 35 infants in the cocaine group were born prematurely, compared with 36 (4%) of the 1021 of those in the no drugs control group ($P < .01$). Prolonged rupture of membranes (>24 hours) was found in 4 of 5 premature cocaine-exposed newborns, 1 of whom had evidence of chorioamnionitis on placental examination. None of the 4 premature heroin-exposed infants had prolonged rupture of membranes, but 1 did have chorioamnionitis.

Meconium staining of the amniotic fluid occurred in 99 (10%) of the 1021 infants in the no drugs control group compared with meconium staining in 12 (34%) of the 35 newborns in the cocaine

group ($P < .0002$), 5 (36%) of the 14 newborns in the heroin group ($P < .01$), 7 (41%) of the 17 newborns in the cocaine/heroin group ($P < .001$), and 6 (30%) of the 20 newborns in the cocaine history group ($P < .05$).

COMMENT

We have shown that prenatal cocaine and/or heroin use is associated with significant abnormalities in the infant, including elevated abstinence scores, growth retardation, microcephaly, prematurity, and meconium staining of the amniotic fluid. The results show that cocaine and heroin appear to be synergistic in causing abnormal behavior of withdrawal; less than 20% of the infants exposed to both cocaine and heroin had Finnegan¹¹ scores of less than 9. This was a significantly greater incidence of abnormal Finnegan scores than had occurred in infants exposed to either cocaine alone or heroin alone. Although we found that infants in both the cocaine group and the cocaine/heroin group had

significant growth retardation compared with a drug-free group, we saw no synergistic effect of cocaine and heroin on the incidence of growth retardation or microcephaly to confirm results of a recent study that showed that abusers of cocaine alone are no more likely than abusers of multiple substances to have growth-retarded infants.¹⁹

There are problems with defining a group of infants exposed in utero to drugs solely on the basis of maternal history. Mothers are well known to be poor historians about their drug use during pregnancy.¹⁴ We feel that in our study the problem of inaccurate histories was decreased by having the maternal drug history obtained by three separate individuals who were experienced in obtaining drug histories. If there were women who had used cocaine during their pregnancies who were incorrectly classified as having used no drugs, this would artificially lower the significance of our findings, rather than contribute to them.

The marked disparity between the results of maternal and neonatal urine drug tests is of special concern. The reason for this disparity is not entirely understood, but may represent individual differences in the metabolism and clearance of the drugs, collection techniques, or sensitivity of the urine screen.^{15,16} We have found that mothers who abuse either cocaine or heroin often abuse other street drugs. The use of thin-layer chromatography as a urine screen in both mother and infant was necessary to screen for all drugs used by the mother before delivery, but many false-negative results may occur secondary to the low sensitivity of the test.¹⁶ We found that in 35% of infants in the cocaine history group, abstinence scores were elevated but urine screen results were negative. Cherukuri et al¹⁷ found that in newborns of mothers who use "crack," 25% were symptomatic but had negative urine screening results, whereas another 35% of newborns had positive screening results and no symptoms of withdrawal using the more sensitive multiple enzyme immunoassay technique urine drug test. The mother's urine was not screened. These findings demonstrate the necessity of obtaining both maternal and neonatal urine drug tests when evaluating an infant for pos-

Fig 2.—Percent of infants born at term with birth weight or head circumference more than 2 SDs below the mean for infants without drug exposure who were delivered during the study period. Asterisk indicates $P < .05$, when compared with the no drugs group by a Fisher Exact Test.

sible drug exposure, but also warn that the results of the urine screen, particularly when negative, must be interpreted in light of the infant's clinical status.

We used the abstinence scoring system devised by Finnegan¹¹ to quantitate the presence and degree of withdrawal. All scorers were trained and were known to be able to score infants accurately. Although they were not blinded to which infants were in the cesarean group and which were in the study group, they were ignorant of the results of the urine tests. That all of the infants in the cesarean group had scores less than 9 suggests that this scoring system reliably separates infants with signs of withdrawal from those without.

It is not clear whether elevated abstinence scores really indicated withdrawal or whether they indicated some other neurologic abnormality. There is considerable evidence that repeated exposure to cocaine can cause long-lasting abnormalities by a mechanism, or mechanisms, other than withdrawal. Cocaine has significant effects on central nervous system dopamine, serotonin, and norepinephrine receptors, as well as on the release of these neurotransmitters.¹⁸ Experiments with animals suggest that repeated doses of cocaine cause a progressively increasing sensitivity to the effects of cocaine on behavior, particularly hyperactivity and co-

caine-induced seizures. This increasing sensitivity of the central nervous system is called the "kindling effect."¹⁹⁻²¹

In our study, mothers using both cocaine and heroin demonstrated synergistic effects on abstinence scores when compared with cocaine or heroin use alone. Pinel and Van Ott²² reported that when a stimulant, such as cocaine, is used repeatedly in animals, an increased sensitivity of the central nervous system results. They found that withdrawal from a second drug is made more severe when combined with the stimulant. It seems reasonable to postulate that chronic intermittent exposure to cocaine might cause a long-lasting impact on the developing fetal brain, and that the addition of heroin might have a synergistic effect resulting in the type of abnormal behavior we observed in these infants. If the fetal brain has been adversely affected by these two drugs, then close follow-up for signs of developmental delay or increased risk for sudden infant death syndrome should be considered.

We defined growth retardation and microcephaly on the basis of the population that we saw during the study period, rather than according to the standard criteria of Lubchenco et al.²³ Because it is well known that life-style can influence a mother's health, we chose to compare our study infants with a population that was as similar as possi-

ble. The mean (\pm SD) birth weight of the infants in our no drugs control group (3.35 ± 0.47 kg) agrees closely with recently published data for a large group of infants born in California.²⁴ Had we defined growth retardation and microcephaly on the basis of the Lubchenco et al growth curves, the differences between the birth weights and head circumferences of the study and the control groups would also have been significant.

Seventeen percent of the newborns in the cocaine group had growth retardation. Twenty-seven percent of the newborns in the cocaine group were microcephalic. Infants in the cocaine history group were less likely to have growth retardation or to be microcephalic than were those born to mothers who had recently used cocaine. This may suggest that continued use of cocaine in the third trimester of pregnancy when the infant is in a phase of rapid growth is a cause of growth retardation. A similar finding has been reported in alcoholic mothers.²⁵

The increased incidence of newborns who were small for gestational age in the cocaine group and who were microcephalic among the cocaine and cocaine/heroin groups could be due to several factors. Cocaine is reported to be an appetite suppressant and may lead to decreased maternal energy intake.²⁶ Fetal growth disturbances could also have been caused by a direct vasoconstrictive effect of cocaine on the placenta.²⁷ Cocaine has been reported to cause placental vasoconstriction, resulting in reduced fetal blood flow and fetal hypoxia.²⁸ Since fetal growth is dependent on adequate placental blood flow, this could account for the growth retardation and microcephaly we noted.²⁹

Eighty-five percent of the mothers who admitted using cocaine reported using freebase (crack) cocaine. Freebase cocaine causes significantly more vasoconstriction than does intranasally ingested cocaine.^{30,31} This could account for the severity of the growth retardation and microcephaly we observed.

Cocaine abusers commonly use other drugs, such as tobacco or alcohol.² Alcohol consumption could play a role in the decreased intrauterine growth of the newborns in the cocaine group, because newborns with fetal alcohol syndrome

also have a small head circumference and a low birth weight.³² However, the urine drug test results in the cocaine group were negative for alcohol, as were most of the maternal histories. None of the infants studied had the typical features of fetal alcohol syndrome.³³ Maternal cigarette smoking can cause decreased intrauterine growth.³⁴ Our crack-abusing mothers reported that they often mixed tobacco and marijuana with their cocaine and smoked it in the form of a cigarette. Our finding of an 82% incidence of tobacco use in our cocaine-smoking mothers agrees closely with the findings of others.¹⁷ Marijuana was found in the urine in 20% of the mothers whose test results were positive for cocaine, which compares closely with a 29% incidence reported by MacGregor et al.¹³

Placental vasoconstriction could also account for the threefold increase in meconium staining of the amniotic fluid we noted in the cocaine group. Fetal hypoxia has been reported to cause meconium staining in infants of heroin abusers.⁶ We did not find a close correlation between our infants with meconium staining and maternal chorioamnionitis.

Infants exposed to either cocaine or heroin have a greater incidence of prematurity than the drug-free infant population.^{6,13} Although chorioamnionitis is a leading cause of prematurity,³⁵ we did not find an increased incidence of clinical chorioamnionitis in the drug-exposed mothers in our study. We did find a high incidence of prolonged rupture of membranes in the infants who tested positive for cocaine (80%) who were premature. Naeye et al⁸ found a 60% incidence of acute infection in mothers who abused heroin, most of whom delivered prematurely. Others have found an increased incidence of premature rupture of membranes in crack-smoking mothers.¹⁷ We did not examine all the placentas of the mothers in our study who used drugs. A closer inspection of the placenta of the mothers who used drugs and delivered either premature or small-for-gestational-age infants might show closer agreement between chorioamnionitis and adverse outcome in this population.

SUMMARY

We concluded that while signs of withdrawal after prenatal cocaine expo-

sure are usually mild, they occur in a significant number of infants. Prenatal cocaine exposure coupled with heroin exposure markedly increases an infant's chances of showing signs of abstinence. Maternal and infant urine screen results may be negative and abstinence symptoms still may be present in the infant. Prenatal cocaine exposure is also associated with a significantly increased risk of growth retardation, microcephaly, prematurity, and meconium staining of the amniotic fluid.

We recommend that both maternal and infant urine be tested when there is suspicion of maternal drug use during pregnancy. All cocaine-exposed infants should also be screened for exposure to heroin and other drugs. We recommend that infants exposed to drugs in utero should be evaluated for signs of withdrawal using a standardized scoring system. Finally, these infants should be followed up closely after discharge from the nursery, as growth retardation, microcephaly, and abnormal behavior may all be suggestive of potential long-term neurologic or developmental problems.

We thank Bertram Lubin, MD, and Marshall Klaus, MD, for their help and suggestions and Ms Phyllis Dyer for her secretarial assistance.

Adolescents and Condoms

Associations of Beliefs With Intentions to Use

Susan M. Kegeles, PhD; Nancy E. Adler, PhD; Charles E. Irwin, Jr, MD

• Sexually active adolescents should use condoms to prevent the transmission of sexually transmitted diseases, including human immunodeficiency virus. This study examined, among male and female adolescents, which beliefs about condoms are associated with intentions to use them if they have coitus in the next year. Teenagers attending adolescent health clinics completed self-administered surveys. Although most adolescents knew that condoms prevent sexually transmitted diseases, an increasing belief in the preventive effects of condoms was not associated with an increased motivation to use them. Instead, other immediate, short-term consequences, such as the ease with which they can be used and discomfort associated with their use, were most strongly associated with adolescents' intentions to use condoms. To encourage condom use, messages from physicians and other health care professionals must focus on adolescents' beliefs that are most likely to encourage or inhibit use of condoms. Health considerations should not be the sole emphasis of such communications if the goal is to increase the use of condoms among sexually active adolescents.

(AJDC. 1989;143:911-915)

There are high rates of sexually transmitted diseases (STDs) among sexually active adolescents, including *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and syphilis.¹⁻⁵ Furthermore, although acquired immunodeficiency syndrome is currently uncom-

mon among adolescents,⁶ there is concern that sexually active teenagers also may be at risk for developing acquired immunodeficiency syndrome or acquiring human immunodeficiency virus infection because of their sexual practices and high rates of STDs.⁷⁻¹⁰

Research indicates that latex condoms, when used correctly, are effective in preventing the transmission of various STDs, including human immunodeficiency virus.¹¹⁻¹⁷ The Surgeon General and the Centers for Disease Control, Atlanta, Ga, have urged all people, including adolescents, to use condoms if they are having sexual intercourse outside of long-standing, established, mutually monogamous relationships.^{18,19} Therefore, physicians and health educators are asked to encourage adolescents to use condoms if the teenagers are having intercourse. Little is known about adolescents' beliefs about the consequences of using condoms, and it is not known what specific beliefs about condoms are associated with intentions to use them. Greater understanding of those beliefs that are associated with intentions to use or not use condoms is an important precursor to developing effective interventions to promote condom use among teenagers.¹⁹

This study examined the extent to which different beliefs about condoms are associated with adolescents' intentions to use or not use them. The Theory of Reasoned Action, which has been used successfully to describe contraceptive and family planning behaviors,²¹⁻²⁴ underlies this research and guided our selection of variables to study in this investigation. Other variables may also affect whether condoms are actually used, such as the individual's ability to get the partner to agree to the use of condoms and the availability of condoms

at the time of intercourse. However, because an individual's intention to use condoms is the most basic variable for subsequent behavior,^{21,22} it is a key focus for intervention.

Most health education messages urging the use of condoms, including communications from physicians, focus exclusively on health aspects. Therefore, it is of particular interest to determine whether adolescents' beliefs about the utility of condoms in protecting them from STDs is associated with their intentions to use condoms. It is also of interest to examine whether concerns about the efficacy of condoms in the prevention of pregnancy are associated with intentions to use them, since beliefs that condoms have high failure rates with respect to contraception might be a barrier to their use.

METHODS

These data were collected as part of a larger study of adolescent decision making regarding contraceptive use in heterosexual sex.²⁵ These surveys were administered from February 1984 to September 1985. Subjects were male and female adolescents aged 14 through 19 years who were coming to one of two adolescent health care clinics in San Francisco, Calif. One clinic was based in a large university medical center and the other was part of Kaiser Permanente.

All teenagers who attended the clinics when an interviewer was present and who met the inclusion criteria for the study were invited to participate. Inclusion criteria were English-speaking, single, not pregnant, and without a developmental disability or a major psychosocial problem. There were frequent delays at the clinics, and the majority of the adolescents who declined to participate in the study cited reluctance to stay for an additional hour beyond their medical appointment. We do not believe that this selection factor is likely to introduce systematic bias to the study findings.

Table 1.—Consequences Rated by Respondents

1. Makes it easy to have sex on the spur of the moment
2. Makes me the one responsible for preventing pregnancy
3. Makes it seem that I am planning to have sex
4. Uncomfortable or painful to use
5. Protects me from venereal disease
6. Easy to use
7. Gives me guilt feelings
8. Decreases sexual pleasure because of feel, taste, or smell
9. Expensive
10. Natural
11. Immoral
12. Inconvenient
13. Clean
14. Used by a lot of people my age
15. Can be used without my partner or me having to see a physician
16. Can be used without my parents' knowledge
17. Keeps me (my partner) from getting pregnant
18. Requires me to have self-control
19. Requires my partner to have self-control
20. Affects my physical appearance
21. Has minor or immediate side effects on my health

The socioeconomic distribution of adolescents attending the clinics was determined by examining the method of payment for visits. At the university-based clinic, 40% of the reimbursement came from Medi-Cal (Medicaid), 30% from a clinical teaching subsidy (partial funding for the visit was provided by a university teaching fund and the remainder was provided by the patient or parent), and 30% from private insurance. The socioeconomic distribution at the health maintenance organization is essentially a middle-class population of adolescents whose parents are employed full time.

Prior to the current investigation, a pilot study was conducted with 60 male and female adolescents from the university-based clinic. In open-ended interviews, subjects were asked to identify the "good" and "bad" aspects of using several different contraceptive methods, including condoms. Responses were compiled and integrated with a list of beliefs about contraceptives culled from the literature.^{23,24,26} A list of 25 consequences was developed from this pilot research, 21 of which are relevant to condoms (Table 1). Subjects rated the likelihood that each consequence might occur if they (or their partner) were to use condoms, withdrawal, the pill, or a diaphragm if they were to have sex in the next year. Surveys were self-administered with same-sex interviewers present to answer questions.

Subjects rated each consequence on a seven-point Likert-type scale that ranged from *very unlikely* (−3) to *very likely* (3) to occur

if the individual (or the individual's partner) used condoms when they had intercourse. Intention to use condoms in the next year if they had intercourse was assessed on a seven-point Likert-type scale ranging from *definitely would not* (−3) to *definitely would* (3) use condoms.

RESULTS

We expected that in addition to beliefs about condoms, gender, ethnic/racial background, prior sexual experience, and prior use of condoms might also influence intentions to use condoms in the next year. To examine the association between beliefs about condoms and an intention to use them above and beyond these influences, the effects of prior sexual experience, prior use of condoms, and racial/ethnic background were controlled for through the use of multiple regression.

The following four-step multiple regression procedure was conducted for each belief: (1) intention was first regressed onto sexual activity, (2) prior condom use was entered next, (3) racial/ethnic background was entered as a set of "dummy" variables²⁷ (note that these three steps were identical for each belief item), and (4) the specific belief item was then entered and the semipartial correlation was examined for statistical significance.

The decision was made not to control for the effects of gender through this procedure, but instead to analyze male and female adolescents separately. The dynamics of condom use may differ greatly for the two genders, and this approach will yield information about which beliefs clinicians and health educators should address for male adolescents and female adolescents in general. Although it would be of interest to examine if the relationship between beliefs and intentions differs by race/ethnicity, our sample size within gender and race/ethnicity was too small to allow for the statistical analyses.

To reduce the type I error rate due to numerous statistical tests, only semipartial correlations that were significant at least at $P < .01$ were interpreted as significant and reported.

To determine the total amount of variation in intentions to use condoms that could be explained by the relevant beliefs, those beliefs found to be significantly related to intentions to use con-

doms were then simultaneously entered as a set into a multiple regression analysis. Beliefs were entered simultaneously because we considered it impossible to determine a priori which beliefs should be entered first in a hierarchical manner.

Only those consequences found to be significantly associated with intentions to use condoms were examined in detail, with the exception of beliefs about the efficacy of condoms to prevent STDs and pregnancy. It is of interest to determine the distribution of those beliefs found to be significantly related to intentions since such information can inform health care providers of which messages might be most effective.

Sample

The sample consisted of 345 female adolescents and 161 male adolescents; 32% (110) of the female adolescents and 43% (70) of the male adolescents were virgins. Of the sexually active adolescents, 59% (139) of the female adolescents and 63% (57) of the male adolescents had used condoms. The mean age of female adolescents was 16.7 years (SD, ± 1.36 years) and of male adolescents was 16.2 years (SD, ± 1.44 years). The ethnic/racial breakdown of the sample was as follows: 35% (179) were non-Hispanic white, 33% (167) were black, 13% (68) were Hispanic, 10% (51) were Asian, and 8% (41) were "other" (mixed or did not report). The educational level of the sample at the time of the study was as follows: 6% (29) were in seventh or eighth grade, 35% (179) were in ninth or 10th grade, 42% (215) were in 11th or 12th grade, 10% (49) were in college or junior college, 2% (11) had dropped out of school, 2% (9) were high school graduates and were not attending school, and 3% (14) did not provide this information.

Female Adolescents

Female adolescents who had not had intercourse were more likely than sexually active female adolescents to intend to use condoms in the next year if they were to have intercourse ($r = .28$, $P < .001$). This is consistent with previous research showing that condoms are frequently used early in one's sexual "career," before moving on to more effective prescriptive methods.^{28,29} Previous condom use, entered next in the

Table 3.—Means, Confidence Intervals (CIs), and Distribution of Beliefs Associated With Intentions to Use Condoms in Female Adolescents

Beliefs	Mean* (95% CI)	% Endorsing†	
		Unlikely	Likely
Spur of the moment	0.90 (0.69, 1.11)	29.0	66.1
Easy to use	1.49 (1.30, 1.68)	15.9	79.5
Inconvenient	0.05 (-0.75, 0.27)	48.7	49.7
Clean	0.64 (0.42, 0.86)	34.2	59.7
Popular with peers	2.05 (1.88, 2.20)	9.2	86.7
Partner needs self-control	1.05 (0.82, 1.28)	25.1	69.0
Protects from venereal disease	1.51 (1.30, 1.72)	17.6	76.7
Can get pregnant	-0.70 (-0.52, -0.88)	62.7	3.6

*The response scale ranged from *very unlikely* (-3) to *very likely* (3) to occur if the individual's partner used condoms when they had intercourse.

†Percentages do not sum to 100 because neutral responses were deleted from the table.

multiple correlation procedure, also was significantly associated with intention to use condoms ($sr = .19$, $P < .001$); prior use was associated with a greater estimated likelihood of future use. Ethnic/racial background was not significantly associated with intentions to use condoms.

After controlling for the influence of sexual activity, prior experience with condoms, and racial/ethnic background,

the following five beliefs were found to be positively associated with intentions to use condoms: they enable one to have sex on the spur of the moment, they're easy to use, clean, popular with peers, and using them requires one's partner to have self-control (Table 2). In addition, considering condoms to be inconvenient was significantly associated with decreased intentions to use them. There was no significant association be-

tween intentions to use condoms and believing that they prevent STDs or that they are effective in preventing pregnancy.

The total R , including sexual activity, prior condom use, and the beliefs about condoms, was statistically significant, and thus showed these factors to be associated with intentions to use condoms among female adolescents ($R = .48$; $df = 8$, 304; $P < .001$). After controlling for the influence of sexual activity and prior condom use, the set of six beliefs explained a significant amount of variation in intentions to use condoms ($sr^2 = .13$, $P < .001$).

Means and 95% confidence intervals (CIs) for beliefs that are significantly associated with intentions are shown in Table 3. Beliefs about the consequences of using condoms were assessed on continuous scales, but for the purposes of descriptive analyses, the scales were collapsed in the following way: scores between 1 and 3 represent beliefs that the particular consequence is likely to occur by using condoms and scores between -1 and -3 indicate a belief that the consequence is unlikely to occur. A score of 0 indicates neutrality with respect to the likelihood that a given consequence will occur.

As shown in Table 3, the greatest consensus among female adolescents was that condoms are popular with their peers (87%), they prevent STDs (80%), and they are easy to use (80%). A majority (66%) believed that condoms enable one to have sex on the spur of the moment, are clean (60%), and require the male partner to use self-control (69%). On the issue of inconvenience, 50% believed condoms to be inconvenient. A sizeable minority of female adolescents (32%) believed it likely that one could get pregnant using condoms.

Male Adolescents

No significant association between sexual activity and intention to use condoms was found for male adolescents, indicating that those who had sex and those who did not differ significantly in their intentions to use condoms if they have sex in the next year. However, prior experience with condoms was associated with future intentions ($sr = .17$, $P < .05$), with male adolescents who used condoms more strongly in-

Table 4.—Means, Confidence Intervals (CIs), and Distribution of Beliefs Associated With Intentions to Use Condoms in Male Adolescents

Beliefs	Mean* (95% CI)	% Endorsing†	
		Unlikely	Likely
Spur of the moment	1.64 (1.39, 1.89)	12.5	82.4
Easy to use	1.85 (1.60, 2.10)	13.2	82.4
Makes me responsible for contraception	2.28 (2.09, 2.47)	4.5	93.1
Painful or uncomfortable	-0.71 (-1.04, -0.38)	58.0	35.4
Popular with peers	2.21 (1.99, 2.43)	6.6	92.7
Protects from venereal disease	2.23 (2.01, 2.45)	6.4	92.9
Can get partner pregnant	-1.69 (-1.93, -1.45)	82.7	10.9

*The response scale ranged from *very unlikely* (-3) to *very likely* (3) to occur if the individual's partner used condoms when they had intercourse.

†Percentages do not sum to 100 because neutral responses were deleted from the table.

tending to use them again than those who had never used them. Ethnic/racial background was not significantly associated with intentions to use condoms.

After controlling for the effects of sexual activity and previous experience with condoms, the following four beliefs were found to be positively associated with intentions to use condoms in the next year: they enable one to have sex on the spur of the moment, they make the male adolescent responsible for using contraception, they're easy to use, and they're popular with peers (Table 2). In addition, the belief that condoms are painful to use was associated with a decreased intention to use them. Among male adolescents, as was found with female adolescents, the intention to use condoms in the next year was not associated with believing that condoms prevent STDs or that condoms are effective in preventing pregnancy.

The total R , including sexual activity, prior condom use, and the four beliefs listed above was statistically significant, and thus showed these factors to be associated with intentions to use condoms among male adolescents ($R = .66$; $df = 7, 128$; $P < .001$). After controlling for the influence of sexual activity and prior condom use, the set of beliefs explained a significant amount of variation in intentions to use condoms ($sr^2 = .40$, $P < .001$).

In examining the means, CIs, and distribution of the beliefs found associated

with intentions to use condoms (Table 4), we found that the vast majority of male adolescents believed that condoms prevent the spread of STD (93%), are popular with their peers (93%), and that using them meant they were the ones responsible for not getting their partners pregnant (93%). Most also believed that condoms are easy to use (82%) and permit spontaneous sex (82%). A considerable minority believed it likely that condoms were painful or uncomfortable to use (35%) and that condoms would not protect against pregnancy (11%).

COMMENT

These data indicate that although most of the adolescents knew that condoms prevent STDs, belief in the preventive benefits of condoms was not associated with increased motivation to use them. Intervention programs aimed at increasing the use of condoms emphasize the effectiveness of condom use in the prevention of transmission of STDs (including acquired immunodeficiency syndrome). This sample appears to have understood this message from the prevention programs; however, it did not enter into consideration for using condoms. Contrary to our hypothesis, concerns about the possible efficacy or inefficacy of condoms in the prevention of pregnancy were also unrelated to intentions to use them.

These findings indicate that health and contraceptive considerations play a

minor role in the decision to use or not use condoms. Instead, a number of other immediate, short-term consequences were most strongly associated with adolescents' intentions to use condoms. Believing that condoms are easy to use and enable one to have spontaneous sex contributed to the intention to use them among both male and female adolescents. Likewise, for both sexes, believing that condom use is popular with peers encouraged their use. Many female adolescents were also motivated to have their partners use condoms because condoms are clean and because using condoms requires that the partner use self-control. The latter point may reflect a desire on the part of female adolescents that male adolescents participate in contraception and not leave the entire responsibility to them.

Interestingly, male adolescents appear to view such responsibility positively; the belief that using condoms makes them responsible for contraception was positively linked to an increased intention to use them. This "symmetry" between the male and female adolescents in their desire for the male adolescents to be more involved with the contraceptive process could provide an important focus of interventions with teenagers.

The primary barrier to using condoms among male adolescents appears to be the belief that condoms are painful, a belief shared by over one third of the sample. Several barriers to using condoms emerged among female adolescents. Nearly half believed condoms to be inconvenient to use. Many female adolescents also considered condoms not to be clean and felt that their use interferes with having spontaneous sex.

These findings suggest that physicians' communications to adolescents and the messages from public health and sex education programs, in addition to emphasizing the health aspects and disease prevention of condom use, must focus on the social and physical aspects of their use. Health considerations do not appear to be a salient dimension of the adolescents' choice to use or not use condoms. This may be particularly true if adolescents do not feel personally vulnerable to STDs and/or do not perceive STDs as a particularly severe health threat.

Since our goal is to encourage sexually active adolescents to use condoms, this study indicates that other positive aspects about condoms should also be emphasized in communications. Messages might focus on the positive aspects of using condoms, such as the shared responsibility for contraception that condom use entails and that rather than interfering with sex, condoms are easy to use, enable spontaneity, and are clean. It would also be of use to point out that many other teenagers also use condoms. To encourage condom use, messages need to take into account what the adolescents already believe, and focus on those beliefs most likely to serve as incentives. Clearly, not all beliefs about condoms are negative. To increase their use among those teenagers who are already sexually active and to reduce the spread of STDs, we must address the concerns that may inhibit their use and emphasize the incentives for use.

Our results also demonstrate that

there continue to be some misconceptions about condoms. Nearly 20% of female adolescents and 7% of male adolescents still do not understand that condoms prevent the transmission of STDs. In addition, some male adolescents believe that condoms are painful. Such misperceptions should be clarified (perhaps including advice to try different brands of condoms that may vary in fit), in addition to conveying the positive messages.

This sample was diverse with respect to socioeconomic status, educational level, and ethnic/racial background and may be quite representative of the kinds of adolescent patients health care providers are likely to see. A higher proportion of female adolescents in this sample were sexually active than male adolescents, as would be expected from a clinic sample, since female adolescents tend more often to seek health care for issues concerning sexuality and reproductive health (contraception or preg-

nancy testing) than do male adolescents. The extent to which the findings from this clinic are generalizable to adolescents not attending health care clinics is not known.

Many female adolescents attending clinics may be seeking to obtain prescriptive methods, including oral contraceptives, and do not intend to use condoms since they are contraceptively protected. Clinicians need to encourage adolescents to continue to use condoms or add condoms to their sexual practices as they initiate prescriptive methods.

Comparison of Amoxicillin and Clavulanic Acid (Augmentin) for the Treatment of Nonbullous Impetigo

Ron Dagan, MD, Yair Bar-David, MD

• We undertook a prospective double-blind controlled study to compare the efficacy of a drug that usually has no antistaphylococcal activity (amoxicillin trihydrate) with the efficacy of the same drug with an addition of a β -lactamase inhibitor (amoxicillin plus clavulanic acid [Augmentin]) in the treatment of nonbullous impetigo. Fifty-one culture-positive patients, aged 6 months to 9 years, were included, 26 in the amoxicillin group and 25 in the Augmentin group. The study groups were clinically and bacteriologically comparable at the start of the study. *Staphylococcus aureus* was isolated from all patients and β -hemolytic streptococcus from 14 (29%). All staphylococci were sensitive to Augmentin but resistant to amoxicillin. Forty-nine patients completed the study. The clinical response was significantly better among the Augmentin recipients (marked improvement in 71% and 95% of patients after 2 and 5 days, respectively; no new lesions during the treatment course) than among the amoxicillin recipients (marked improvement in 44% and 68% of patients after 2 and 5 days, respectively; new lesions appeared in 20% of patients). Recurrence within 3 weeks occurred in 12 (26%) of 49 patients, and no difference was observed between the two groups. We conclude that *S aureus* is common in nonbullous impetigo, and that at least in some cases it plays an important role in the course of the disease that can be altered by specific therapy.

(AJDC. 1989;143:916-918)

The role of systemically administered antibiotics in the treatment of impetigo is well established. This mode of treatment is usually superior to local treatment.¹⁻⁴ However, controversies still exist over the optimal systemic anti-

biotic to be used. It is well established that *Staphylococcus aureus* can be isolated from a substantial number of impetiginous lesions, either as a single pathogen or in conjunction with streptococci.^{1-3,5-8} However, its causative role and hence the necessity to administer penicillinase-resistant drugs is still debated. While *S aureus* has been regarded as a "secondary offender" by many authorities who claim that it plays no important role in the disease,⁹⁻¹⁴ others believe that *S aureus* is important and may even be the sole infecting organism in this type of skin infection.^{7,8,15}

We therefore undertook a prospective double-blind controlled study to compare the efficacy of a drug, which in our community usually has no antistaphylococcal activity (amoxicillin trihydrate), with the efficacy of the same drug with an addition of a β -lactamase inhibitor (amoxicillin plus clavulanic acid [Augmentin]) in the treatment of nonbullous impetigo.

PATIENTS AND METHODS

We included in the study infants and children under 13 years of age presenting with nonbullous impetigo at two pediatric clinics in the Negev region of Israel, from May 15 to October 31, 1987. These clinics generally serve a population with crowded households that belong to lower social middle classes.

The following data were recorded before the initiation of treatment: patient age, the presence of fever (temperature $\geq 38^{\circ}\text{C}$), number of lesions, diameter of the three largest lesions, and the presence of regional lymphadenopathy.

The three largest lesions were cultured as follows: The corner of the crust was lifted to reach the fresh exudate underneath. The lesion was then touched by a sterile cotton swab and immediately streaked onto a 5% sheep blood agar plate, which was transferred to the clinical bacteriology laboratory in Soroka Medical Center, Beer Sheva, Israel, on the same day. Concomitantly, a second

set of cultures was transferred to the laboratory in a transport medium (Culturette, Marion Scientific, Kansas City, Mo).

After obtaining the cultures, patients were randomized to receive either amoxicillin trihydrate syrup (40 mg/kg per day, three times a day) or amoxicillin/clavulanic acid (Augmentin) syrup (40 mg/kg per day of amoxicillin trihydrate and 10 mg/kg per day of clavulanic acid, three times a day) in a double-blind fashion.

The patients were followed up on days 2, 5, and 10 and evaluated for (1) the morphologic structure of the lesions (on day 2, the grades were markedly improved, slightly improved, or not improved; on days 5 and 10, the grades were cured, markedly improved, slightly improved, or not improved), and (2) the appearance of new lesions.

The definitions for improvement were as follows: cured, lesions disappeared or were completely dry; improved, lesions were less extensive or some were dry, but at least some were still not completely dry; and not improved, lesions were as before treatment or worse. In addition, on days 2 and 5, the physician had to decide whether a repeated culture was needed (given that the lesion was not completely dry).

Compliance was assessed by the amount of drugs left in the bottles at each visit. The patient was contacted by telephone again after 3 weeks to determine the recurrence rate of the infection. If impetigo recurred (as defined by new lesions), the patient was seen in the clinic and treated with cephalixin.

Bacteria and Sensitivity

The presence of group A streptococcus was screened by bacitracin disk (0.04 U) after incubation in 5% carbon dioxide for 18 to 24 hours. Confirmation was performed using specific serotyping (Wellcome Diagnostics, Dartford, England).

Identification of *S aureus* was based on colony structure, pigment, and hemolysin production. Confirmation was performed by the slide coagulase technique. Antibiotic susceptibility was performed by the method described by Bauer et al.¹⁶ Statistical analysis was performed by Fisher's Exact Test. $P < .05$ was considered significant.

Accepted for publication January 20, 1989.

RESULTS

During the study period, 52 patients were enrolled. Culture was positive in 51 patients who constituted the study group, 26 in the amoxicillin group and 25 in the Augmentin group. The two study groups were not significantly different in their age, distribution, the presence of fever, number and diameter of the lesions, the presence of regional lymphadenopathy, and culture results (Table 1).

Staphylococcus aureus was isolated from all 51 patients with positive culture. From 14 (29%) of 51 patients, a β -hemolytic streptococcus was also isolated: group A streptococcus from 11, group G streptococcus from 2, and

group B streptococcus from 1. All streptococci were sensitive to both amoxicillin and Augmentin. All staphylococci were resistant to penicillin and amoxicillin, but sensitive to Augmentin. In 16 (32%) of the 51 patients with staphylococci isolated, organisms were resistant to erythromycin. Two patients were dropped from the study after initiation of treatment: one in the Augmentin group was unavailable for follow-up, and another in the amoxicillin group developed severe side effects. All other patients completed the 10-day course and were judged to be compliant. Side effects were noted in 2 (8%) of 26 patients in the amoxicillin group (vomiting in 1 patient and diarrhea in the other). Side effects were not noted in any of the

25 Augmentin recipients.

The course of the disease after initiation of treatment in the 49 patients who were available for follow-up is presented in Table 2. It is clearly seen that the rate of clinical improvement and cure rates were markedly higher in the Augmentin group than in the amoxicillin group. Furthermore, 20% of patients in the amoxicillin group developed new lesions during treatment vs 0% in the Augmentin group. Twenty-four percent of the patients in the amoxicillin group were still culture-positive after 5 days of treatment vs only 4% in the Augmentin group. All positive lesions after initiation of therapy yielded *S aureus*.

Impetigo recurred within 3 weeks in 12 (26%) of 49 patients—6 of 25 patients in the amoxicillin group and 6 of 24 in the Augmentin group.

COMMENT

We have shown in the present study that *S aureus* is present in most cases of nonbullous impetigo in our region and that systemic treatment with a drug with an antimicrobial spectrum that includes *S aureus* is indicated in such an epidemiological setting.

For many years, impetigo had been considered a streptococcal disease.⁹⁻¹⁴ However, *S aureus* has been constantly isolated in a high proportion of impetiginous lesions, and in several recent studies, it was present in over 90% of the cases while *Streptococcus pyogenes* was isolated in about one of three of the cases, usually together with *S aureus*.^{7,17} In fact, a review of 17 studies

† $P < .01$ between amoxicillin and Augmentin groups.

from Europe and the United States revealed that in less than 35% of the cases streptococcus was the sole isolated organism. In contrast, in 16 of 17 studies *S aureus* was isolated alone or with streptococcus from 65% to 98% of the cases.⁷ Furthermore, it was previously shown that lesion morphologic study could not accurately determine whether a particular patient had streptococcal or staphylococcal pyoderma and that *S aureus* predominated in all four morphological forms of impetigo (vesicular, bullous, pustular, ecthymatous, and erosive).^{7,11,14} The facts reviewed above suggested that there is an overall change in the origin of impetigo and that at the present time *S aureus* is becoming dominant, causing lesions that cannot be differentiated from those caused by group A streptococcus. Therefore,

several authors have claimed that drugs with activity against both streptococci and staphylococci should be considered in impetigo.^{7,8,14} To the best of our knowledge, our study is the first to blindly compare a regimen active against both staphylococci and streptococci vs a regimen active against streptococci only.

It may well be that impetigo is still primarily a streptococcal disease and that staphylococci are indeed secondary invaders, maybe playing only a minor role in the pathogenicity. Contributory to this opinion is the fact that a marked improvement as early as after 2 days was observed in 44% of the amoxicillin-treated patients, with a total cure rate of 80%, despite the uniform presence of staphylococcus. However, our results suggest that, at least in some cases, staphylococci do play an important role

in the course of the disease that can be altered by specific therapy.

It is interesting that the recurrence rate within 3 weeks was similar in the two treatment groups. This suggests a reinfection rather than a partially treated situation.

We conclude that in areas where *S aureus* is usually penicillin resistant, the empiric therapy of impetigo should include a drug that is active against both staphylococci and streptococci. In view of recent success with a new topical drug active against both streptococci and staphylococci, namely, mupirocin,¹⁷⁻¹⁹ the role of appropriate topical drugs should be assessed.

Statistical analyses were performed by Lily Neuman, PhD, from the Clinical Epidemiology Unit, The Ben-Gurion University of the Negev.

A Model to Determine the Feasibility of a Pediatric Practice

Kimball A. Miller, MD, MSHA; Deborah A. Miller, MS; Gerald A. Doeksen, PhD; Patti Jacobs

• A major concern of urban and rural citizens of the United States is the availability of adequate pediatric health care in their community. Community leaders attempting to recruit health care providers and pediatricians considering locating their practice in a specific community need a method by which they can evaluate a community's potential for supporting a new primary care practice. A detailed survey was conducted in early 1988 of pediatric practices geographically dispersed throughout the state of Oklahoma. Data collected from the physicians and their administrative staff reflected the volume of office and hospital visits and practice costs over the prior 12 months. Using the capital costs and direct operating cost data with information obtained on the number of patient visits and revenue generated collected in this survey, we designed a model to project the economic feasibility of establishing a pediatric practice in a specific community. This model can be used to project the number of annual pediatric primary care visits a community can generate, the direct and indirect costs to establish and maintain a clinic, and the gross revenue and net income of the practice.

(AJDC. 1989;143:919-923)

Pediatricians are being solicited by community leaders and health care administrators of many small and me-

each of their location options with regard to the potential survival and growth of a new primary care pediatric practice. To this end, pediatric residents completing training and community leaders in Oklahoma have sought assistance from agencies experienced in physician placement, health care design, and economics to help them determine a nonmetropolitan community's ability to support a primary care physician. To achieve this goal, personnel from the Oklahoma state universities and medical schools have worked together to design a model to be used with prospective pediatricians and community leaders for estimating a community's patient primary care needs and the economic feasibility of a practice. Our objective is to explain the research method and the model derived from a survey of geographically diverse, established pediatric practices.

Various publications have previously outlined several necessary steps in selecting a site for a medical practice. Researchers such as Balliett¹ have suggested selecting a practice site by investigating a selected population's income levels, projected changes in an area's population, and the historical ability of the members of the community to pay for medical services. Donohugh² advises consulting a table illustrating the population-to-physician ratios for specific specialties to determine the area's needs and a comparison to national norms. Cotton³ suggests using a location scoring method taking into consideration such factors as local and regional medical facilities, community economic background and growth, and stable community resources that include public schools, recreation facilities, and housing. Furthermore, the recommended guidelines of the American Academy of Pediatrics, Elk Grove Village, Ill, in terms of the population required to support a pediatrician, suggest that one physician is needed per 2500 children

less than 18 years old.⁴

The need for developing an economic model for analyzing practice sites in nonmetropolitan Oklahoma communities was first identified by Doeksen and colleagues,⁵ who investigated the costs of establishing a community clinic. In 1983 Williams and colleagues⁶ collected basic financial data from 16 primary care physicians through the use of structured interviews. This model was later expanded to include the observations of 25 primary care physicians in 1987, which then formed the database to allow a physician, community leader, or other health professional to evaluate the economic feasibility of a potential practice site.⁷

SURVEY METHODS

Recognizing a need to modify this 1987 primary care provider model to take into consideration the unique practice requirements of pediatricians, we designed a pediatric care model and conducted structured interviews with Oklahoma pediatricians and their administrative staff in the spring of 1988.

The pediatricians surveyed geographically represented all areas of the state and were selected to include new pediatricians (in practice <2 years) and established pediatricians. Based on these criteria, the research team selected 10 pediatricians practicing in Oklahoma, all of whom completed the interviews and data collection forms.

Of the 10 surveyed physicians, 5 were in solo practices, 3 were in partnerships, and 2 were in a multispecialty group or association. Seven had been in practice more than 2 years. All were located in nonmetropolitan communities of less than 100 000 population as follows: 2 in communities of less than 5000, 4 in communities between 25 000 and 50 000, and 1 in a city of more than 50 000. The extensive survey questionnaires were administered personally by members of the research team to each physician and designated practice administrator.

To develop a model that could determine a community's ability to support a pediatrician or an additional pediatrician, we needed information on the number of pediatric pri-

mary care visits a practice area will generate, the average number of annual pediatric visits per provider, the capital and operating expenses of a practice, and a projection of gross revenue and net income generated by a specific number of primary care visits.

Primary Care Visits per Practice Area and Physician

Although information on the frequency of visits to physicians and the number of office visits per year categorized by patient age and sex was not available specifically for Oklahoma, national rates were available from a national survey of ambulatory care conducted by the US National Center for Health Statistics, Washington, DC.⁸ The national data were used to determine the number of visits that would be expected from a community or geographic practice area (Table 1).

To obtain data regarding the average number of visits per primary care provider, specific Oklahoma data were obtained using the above survey method. The case study of the 25 family practice physicians conducted in 1987 and the present study of 10 pediatric physicians provided information on the number of office visits, hospital visits, and nursery visits for physicians providing pediatric health care.

Based on observations of the seven established pediatric office practices, the average number of annual pediatric office visits per physician was 5163. This number approximates the published national norm of visits to pediatricians in nonmetropolitan areas, which is 5177.⁸ While the established pediatrician will average 430 monthly visits, the average for a new pediatrician did not approach this level. The average number of monthly visits for the three new pediatricians was 60 for the first month, 119 for the fourth month, and 203 for the seventh month. Of special interest is the range of visits for each month. In every case, the highest number for every month was at least three times that of the lowest number, which illustrates the wide variation in the number of patient visits individual beginning pediatricians will most likely experience. Furthermore, new pediatricians in solo practice seem to have fewer visits during the early months of practice than new pediatricians joining a group practice.

The number of office, hospital, emergency department, nursery, and after-hours clinic visits were averaged for the new and established pediatricians. Furthermore, because of the different types of visits and rates of reimbursement, office visits were subdivided as initial (new patients) or routine (regular patients/follow-up visits). Even though some physicians may choose to limit the number of new patients, we determined in this study that an average of 15% of a physician's

Table 1.—Number of Primary Care Visits by Gender per 100 Population, United States, 1981*

†Calculated by dividing the number of office visits to pediatricians by the percent seen by a pediatrician.

Table 2.—Average Number and Range of Annual Pediatric Office, Hospital, Emergency Department, Nursery, and After-Hours Clinic Visits for Oklahoma Pediatricians, 1988

Type of Visit	No. of Observations	Average	Range	
			Low	High
Office	7	5163	3937	6500
Emergency department	6	146	50	500
Hospital	6	176	50	439
Nursery	6	303	0	800
After-hours clinic	6	120	0	600
Total Encounters	...	5908	4037	8839

office practice consisted of initial visits. Data from the survey determined that 3.4% of the physician office visits would give an estimate of the number of hospital visits. Likewise, 2.8% of office visits yields an estimate of emergency department visits, and 5.8% of office visits estimates nursery visits. Additionally, the survey data indicate that pediatricians can expect that 5% of their office visits will result in roentgenogram charges if the practice has roentgenogram facilities, and 43% of total office visits produced patient fees (laboratory or office procedures) in addition to the standard fee for the office visit. Therefore, as illustrated in Table 2, the typical surveyed pediatrician annually had 5908 patient encounters with a range from 4037 to 8839.

Capital and Operating Expenses

To obtain data on practice capital costs, a complete inventory of all furniture and equipment found in each office (business office, laboratory, examination rooms, reception room, conference room, and physician's office) was completed by a research team member. If the physician knew the cost of the equipment, that information was included. In other cases, however, dealers of capital equipment were interviewed to obtain an average cost of each item found in the practice. With regard to physical plant cost, the physician provided either construction costs with

specific loan terms or annual rental payment data. Furthermore, to develop the database concerning operating costs, four aspects of the practice (personnel, building, office, and medical costs) were evaluated. Personnel costs included wage and benefits for professional and support staff; insurance, taxes, utilities, and maintenance comprised the building costs; office expenses were those associated with the business office operations, professional expenses, and malpractice insurance; and medical costs referred to laboratory and medical supplies used in the provision of patient care.

Regarding the second category of survey research data, capital and operating costs, the survey indicated that a solo pediatrician utilized approximately 1300 to 1600 sq ft of space. The data also indicate that space requirements varied with the number of providers within a practice. For example, approximately 900 sq ft of additional space is needed for a third member. Depending on the clinic, this may include examination rooms, business office, reception areas, laboratory, and conference areas. To arrive at an average for capital costs, survey information from both the 1987 and 1988 studies was used. The surveyed physicians, for whom there was accurate data, had an average of \$97 500 invested in buildings, \$11 000 in land, and \$25 762 in equipment. For practices that rented space, the monthly charges varied

from \$100 to \$2200 depending on the lease (Table 3). As for operating costs, information on the building, office, personnel and medical supply costs was obtained from the pediatric physicians. Their average annual operating cost was \$76 276 per provider (Table 4). These figures reflect costs in nonmetropolitan parts of the Midwest and would have to be adjusted for different parts of the country.

Gross Revenue and Net Income

The gross revenue data were obtained by documenting the amount charged for specific types of visits, procedures (ie, roentgenograms, injections), and laboratory services. The amounts were then modified to reflect current collection rate and third-party payer reimbursement plans.¹⁰ The average, low, and high fees charged for 16 of the most common types of services were tabulated (Table 5). These charges were then multiplied by the number of visits in each category and modified using information on collection rates that were obtained from the physicians. The determination of net income was derived by subtraction of annual operating costs and capital cost from the gross revenue modified by collection rates.

MODEL

Based on the data from the 1987 and 1988 studies, we designed a model for physicians and community leaders to use in determining the economic feasibility of establishing a pediatric practice in an area. The basic parts of the model are (1) a procedure to estimate the annual number of pediatric primary care physician visits and number of providers needed in the service area, (2) a procedure to estimate operating and capital costs for provider (capital costs are converted to annual costs by assuming that the physician takes a loan and pays principal and interest charges), (3) a method to project gross revenue modified for collection rates, and (4) a determination of net provider income.

The model has been developed as a series of 11 forms with 17 pages of explanation to help the user complete the feasibility study. We will illustrate the model by discussing in detail the procedure to estimate the number of primary care physician visits and providers needed in a service area, but other parts of the model will be summarized.

The first step in determining potential demand for primary care physician services in a community is to estimate the number of local office visits for all types of physicians. National survey data give the number of predicted office visits to the provider by gender per 100 population (Table 1). Applying this data, female patients who are 1 year of age would generate a total of 360 per 100 or 3.6 office visits per year. Table 6 includes the utilization rates for all the gender and age

categories in a pediatric practice for a theoretical small community and serves as an illustration of how an estimation of the primary care office visits is generated. To derive this information, one would determine the service area of the community and estimate its population using community census data. These data are available from state and local agencies.

Examples of agencies providing this information at the local level include Chamber of Commerce, community school district office, area planning agency, county medical society, and community hospital administrative staff. State resources of information include state and private medical schools, universities, and economic development agencies. The service area is determined by identifying the location of physicians in surrounding communities. If the communities are the same size, it is assumed that the service area extends halfway between the communities. If the communities are larger, it is assumed that the larger communities have a larger service area based on population size. For example, if one is twice as large as the other, the service area extends twice as far. In addition, local conditions, such as geographic boundaries, transportation capabilities, and the type and number of providers in the surrounding communities, are also used if they warrant consideration.

After the total population of the service area has been categorized by age and gender, the user multiplies the group totals by the utilization rates from the national survey.⁸ This same procedure is continued for each service category, and the total number of physician visits is calculated. According to the national ambulatory care study,⁸ when visits to the four primary care specialties (family practice, internal medicine, pediatrics, and obstetrics and gynecology) are totaled, 71% to 91% of all office visits are handled by these physicians (Table 7).

Once the potential number of local primary care office visits is estimated, a method is needed to determine the number of pediatricians that can be supported in the area (Table

Table 7.—Percent Distribution of Office Visits by Physician Specialty, by Selected Ages of Patients, United States, 1980 to 1981*

Table 8.—Estimated Number of Pediatricians an Area Can Support

1. Estimated total office visits for local area (from Table 6)	4976
2. Office visits to physicians or pediatricians already practicing in area (if unknown, calculate as follows: No. of full-time equivalent pediatricians × 5163 office visits + No. of full-time general and family physicians × 0.22 × 4600 office visits)*	0
3. Remaining potential office visits in service area (item 1 - item 2)	4976
4. Average No. of office visits per pediatrician (research determines this to be 5163)	5163
5. No. of additional pediatricians area could theoretically support (item 3/item 4)	0.96

*Data indicate that 22% of the primary care visits for children under age 14 years go to general and family physicians.

8). To do this, the average annual number of office visits for established pediatricians is used in the determination. Data from a national study conducted in 1985 show the average number of office visits per year was 5177, which was confirmed by the 1988 Oklahoma pediatrician study. To determine the number of pediatricians an area can support, the number of local office visits must be generated and modified by consideration of the number of family practice physicians and other primary care providers. This number

of office visits is then divided by the annual average number of visits per pediatrician to determine an estimate of the number of pediatricians that an area can support.

In the second part of the model, the user estimates all costs associated with the practice. The forms will estimate annual capital costs, principal and interest, and all operating costs by department (personnel, building, office, and medical).

The third part of the model uses the number of visits estimated and data on numbers

Table 9.—Estimated Number of Pediatric Visits by Service Category*

Category of Service	No. of Visits
Initial office visits 0.149 × 4976 total office visits	741
Routine office visits 0.851 × 4976 total office visits	4235
Visits with additional charges (not roentgenogram) 0.43 × 4976 total office visits	2140
Visits with roentgenogram charges If no roentgenogram facilities, proceed to next item Clinic with roentgenogram facilities 0.05 × 4976 total office visits	249
Hospital visits 0.034 × 4976 total office visits	169
Emergency department visits 0.028 × 4976 total office visits	139
Nursery room visits 0.058 × 4976 total office visits	289
After-hours clinic visits 0.023 × 4976 total office visits	114

*Total office visits should be taken from Table 6 or, if more than one physician can be supported, the average of 5163 visits.

of different service categories of visits to project the total number of outpatient and inpatient visits generated in the community (Table 9). These results are multiplied by alternative charge rates to estimate total fees charged. The model uses the survey average, high, and low charge rates, modified to reflect, if known, the usual and customary charges in the community. The user assumes a collection rate to estimate gross income, which can be obtained by visiting local physicians, community hospital administrators,

and business managers in the area. If no physicians are available, the model allows for default collection rates. Subtracting the estimated annual capital and operating costs from the estimated gross income yields an estimate of net income per pediatrician.

COMMENT

Using the model described here and information on the composition of the medical community, a user can project

the economic feasibility of establishing a pediatric practice in a specific nonmetropolitan community. Such information is valuable for pediatricians who are considering relocating their practices or residents who are considering beginning a practice. This model also helps community and hospital leaders who wish to recruit a pediatrician because it provides both parties with objective data. Since the first model was completed in early 1986, more than 50 such studies have been done at Oklahoma State University, Stillwater, and the University of Oklahoma College of Medicine, Tulsa. Residents completing their pediatric and family practice training at the University of Oklahoma Health Science Center-Tulsa, are taught to use the model when they are deciding on their medical practice site. Guidebooks were written to give detailed results of the 1987 family practice and 1988 pediatric surveys, and a computer program has been designed to aid users in completing a feasibility study.⁷ Residents who have used this feasibility model to choose practice sites are being monitored over time to determine the practicality of this modeling method and to offer suggestions of modifications for future revisions.

The Pediatric Marketplace

Gilbert A. Martinez, Alan S. Ryan, PhD

• This study presents an overview of the demography of office-based pediatricians, trends in the patient population, and the growth of the pediatricians' market share of children seeking primary medical care. The following four factors bear directly on the present and future status of the office-based pediatric practice: (1) size of the office-based pediatrician population, (2) size of the pediatric patient population, (3) the frequency of patient visits, and (4) the pediatric market share. Results indicate that the pediatricians' market share of young children has continued to grow. However, the pediatricians' share of young children has not grown fast enough to offset an increase in the pediatrician population. Continued growth of the pediatric practice may depend on developing effective marketing strategies and providing more primary care to the adolescent population.

(AJDC. 1989;143:924-928)

Several studies have centered on the future of pediatrics and the future scope of the pediatric practice.¹⁻⁴ Many of these findings, presented as editorials, describe the issues that must be addressed to meet the needs of the future pediatrician to ensure their place in a changing health care system. In the interest of providing the pediatric community with information concerning the

See also p 919.

status of pediatric practice, we briefly describe trends in the demography of the pediatrician and patient populations together with trends in the pediatricians' market share of the patient population, yielding a description of where pediatricians have increased their share of the patient population seeking primary medical care. We also consider important marketing issues that bear on the future of the pediatric practice.

MATERIALS AND METHODS

Data used in this study were derived from three separate sources. Each is briefly described below.

Pediatrician Population Characteristics

Since the establishment of the Physician Masterfile⁵ in 1906, the American Medical Association (AMA) has been the principal source of information concerning the location, specialty, and activities of physicians. The Physician Masterfile contains current and historical descriptive data on all physicians in the United States and its possessions. The masterfile includes members and nonmembers of the AMA, and those who were and were not certified by their corresponding specialty board. The *Physician Characteristics and Distribution in the US*,⁶ published yearly, summarizes the data compiled in the masterfile.

A file is started on each individual on entry into medical school, or in the case of foreign or Canadian medical graduates, on entry in the United States. Every 4 years, a mail questionnaire, the Physician's Professional Activities (PPA) is sent to all physicians residing in the United States and to US physicians residing temporarily overseas. Each physician is asked to indicate the number of hours worked per typical week within the following categories: professional activity, specialization, and present employment.

Regarding the specialty classification, each physician is asked to indicate the hours spent in primary, secondary, and tertiary activities. A primary specialty is defined by the AMA "as that discipline in which the largest number of hours are reported by the physician on the PPA questionnaire."⁶ Only primary specialties are considered in the *Physician Characteristics and Distribution in the US* publication.

Using information provided by medical schools, hospitals, medical societies, national boards, state licensing agencies, etc, the masterfile is continually updated to reflect the most recent change in address and specialty or professional activity. For a more detailed description of the AMA Physician Masterfile and its contents see the latest edi-

tion of *Physician Characteristics and Distribution in the US*.

This article considers office-based physicians who indicated that pediatrics was their primary specialty during the years 1976 to 1977, 1983 to 1984, 1985 to 1986, and 1987.

The physician's major professional activity as determined from the PPA was divided into two categories—patient care and non-patient care. Patient care included office-based and hospital-based practices (physicians in residency training and full-time members of hospital staffs). Non-patient care activities included administration, medical teaching, research, and other activities. Retired physicians, semiretired physicians, and physicians who indicated that they were inactive for any reason were classified as inactive. This article considered only those physicians who indicated that they had an office-based practice. Included in the office-based practice category were physicians in health maintenance organizations (HMOs), individual practice associations (IPAs), and preferred provider organizations (PPOs).

As defined by the AMA, the field of pediatrics included the following designated subspecialties: adolescent medicine, neonatal-perinatal medicine, pediatric endocrinology, pediatric hematology-oncology, and pediatric nephrology. Pediatric allergy and pediatric cardiology are considered by the AMA to represent separate and distinct medical specialties; these were not considered subspecialties of pediatrics. Thus, physicians who indicated that their primary specialty was either pediatric allergy or pediatric cardiology were excluded from this report. However, in the initial stages of our analyses, we considered the small sample of pediatric allergists and pediatric cardiologists (approximately 380 each). Data based on these groups did not add any new information to the findings concerning the field of pediatrics as defined by the AMA. Pediatricians residing overseas in a US possession also were not considered in this report.

Pediatrician Patient Visits

Each quarter, the Pharmaceutical Database Division of IMS (International Marketing Services) America Ltd publishes the *National Disease and Therapeutic Index*

Fig 1.—National births (in thousands) from 1966 to 1987. Note that during the last 20 years the fertility rate of women of childbearing age has decreased from 90.8 per 1000 in 1966 to 66.1 per 1000 in 1987.

Fig 2.—Number of newborns per office-based pediatrician since 1966 and projected to 1991.

(NDTI).⁶ Based on an audit of office-based physicians, estimates of total patient visits, diagnoses, and drug use are produced. These data are proprietary, and businesses may purchase the NDTI from IMS America Ltd.

Quarterly, a stratified random sample of physicians is initially approached by letter concerning the nature of patient visits from IMS America Ltd. The letter is followed up by a telephone call. Physicians are asked to report on each patient seen or contacted in any way during a 48-hour reporting period. Report forms with instructions are then sent by mail to the physician. The physician is asked to report characteristics of each patient seen, the diagnosis or reason for the visit, and the drug therapy issued. To maintain confidentiality, the names of patients are not reported.

Each quarter, data obtained from more than 2000 physicians are reported. Approximately half the sample is replaced by different physicians each quarter. All office-based physicians are represented within the NDTI sample. The source of physician names is the AMA Physician Masterfile. Of the 2000 physicians surveyed each quarter, more than 140 are pediatricians. For 1987, the sampled pediatricians represented the total population of 22 945 (estimate provided by AMA) office-based pediatricians who reported approximately 132 million patient visits. However, because the sample of pediatricians surveyed was small, to help reduce potential sampling error, this article considers the estimated total number of pediatrician patient visits averaged during 2-year intervals: 1976 to 1977, 1983 to 1984, and 1985 to 1986. We also considered the most current data available, information collected in 1987. A more detailed description of survey methodology and the precision of the estimates can be found in the latest *National Disease and Therapeutic Index*.

Office-Based Pediatrician Potential Market Size

The US Bureau of the Census publishes monthly and yearly estimates of the population of the United States.⁷ The estimates are based on data derived from a variety of sources (see *Current Population Reports*⁷ for a complete discussion of the procedures used in deriving these estimates).

The potential market for pediatric care was calculated by considering the US population of children aged 0 to 2, 3 to 9, and 10 to 19 years average during the 2-year intervals of 1976 to 1977, 1983 to 1984, 1985 to 1986, and during 1987. We used 19 years of age as a cut-off point to assess the US population of children.

The pediatric market share was computed by dividing the number of office-based pediatricians' patient visits by the total number of patient visits (children seeking primary medical care from physicians in any specialty).

RESULTS Demography of the Pediatrician Population

Over the past decade, the population of office-based pediatricians has increased almost twofold from 13 340 in 1976 to 1977 to 22 945 in 1987 (Table). During 1976 to 1981, the compound growth rate was 8%. During 1982 to 1987, this rate was 4%, and the annual growth in 1987 was 4%. If the rate of growth of office-based pediatricians continues at 4% annually, by 1991, we estimate that there will be about 26 800 office-based pediatricians.

During 1981 to 1986, the highest rate of growth of office-based pediatricians (5.0%) occurred in the American Acade-

my of Pediatrics (AAP) district IV⁸ (Florida, Georgia, Kentucky, North Carolina, Puerto Rico, South Carolina, Tennessee, and Virginia). The lowest rate of growth (3.0%) occurred in AAP district V (Indiana, Michigan, and Ohio; pediatricians residing in Ontario, Canada, were not considered).

Pediatric Market: Changing Patient Demography

Recent changes in the demographics of the child population for which pediatricians provide primary medical care have been substantial. These changes correspond to or "echo" those of the postwar baby boom (Fig 1).⁹

The number of births has gradually increased since 1976 and is expected to continue to increase at about 1% annually. Concurrently, there has been a recent, slight decrease in the fertility rate of women of childbearing age (15 to 44 years old; 67 per 1000 in 1981 to 66 per 1000 in 1987). Despite the decrease in the fertility rate, births continue to increase because there are now more women of childbearing age. Echoing the baby boom, the population of young children (<5 years old) will expand reaching its peak in 1990; meanwhile there will be an absolute decline in the adolescent population of 15- to 19-year-olds. The population of adolescents began to fall during the 1970s, shortly after the birth rate reached its peak during the postwar period. The adolescent population will crest in 2005 resulting from the population peak of young children in 1990. Consequently, pediatricians may

†Provided by the American Medical Association.

‡Pediatric market share equals the number of office-based pediatrician patient visits divided by the total number of all patient visits (children seeking primary medical care from physicians in any specialty; not shown in this table).

"recognize a 'wave' in the age distribution of their patients."¹¹

During the last 5 years (1982 to 1987), the highest compound growth rate in the number of US births (50 states) occurred in AAP districts IX (California) (2.6%) and I (Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, and Vermont; Canadian births were not considered) (2.4%). The lowest compound growth rate in the number of births occurred in AAP districts VI (Illinois, Iowa, Kansas, Minnesota, Missouri, Nebraska, North Dakota, South Dakota, and Wisconsin) (-1.2%) and VII (Alabama, Arkansas, Louisiana,

Mississippi, Oklahoma, and Texas) (-1.2%).

The number of newborns per office-based pediatrician has substantially decreased from 361 in 1966 to 167 in 1987. If the rate of growth of office-based pediatricians continues at 4% annually and the number of births increases at 1%, the number of newborns per pediatrician will drop to 149 by 1991 (Fig 2).

Although the total number of pediatrician patient visits among children younger than 20 years has substantially increased, from approximately 93 million during 1976 through 1977 to more than 132 million in 1987, the increase in

the number of pediatricians resulted in a decline in the number of patient visits per office-based pediatrician (from 6969 in 1976 through 1977 to 5774 in 1987) (Table). Additionally, noticeable differences are apparent in the number of patient visits per office-based pediatricians according to the age of the patient (Table). Not surprisingly, more children younger than 2 years were seen by a pediatrician as compared with children in older age groups. In 1987, children younger than 2 years were seen at a rate of 593 visits per 100 children. For children aged 3 to 9 years, the rate was 175 visits per 100 children, and for chil-

dren aged 10 to 19 years, the rate was only 67 visits per 100 children.

Pediatric Market Share

The pediatricians' market share of children through 19 years of age (Table) has steadily increased. The office-based pediatricians' market share of children younger than 2 years has increased from 65% in 1976 through 1977 to 72% in 1987. In 1987, children younger than 2 years represented almost half of all pediatrician patient visits. For children aged 3 to 9 years, the pediatricians' market share increased from 47% in 1976 through 1977 to 55% in 1987. The 3- to 9-year-old group comprises about one third of all pediatrician patient visits. The pediatricians' share of the adolescent patient market (ages 10 to 19 years) is relatively small: 16% in 1976 through 1977 and 24% in 1987. This age group represents only 18% of the pediatrician case load.

Potential Marketing Strategies

In discussing potential marketing strategies for the office-based pediatrician, we have selected several key factors that may affect the future role of the pediatrician in providing care to the traditional market population (infants and young children) and to a growing new market (adolescents). The future office-based pediatrician may face losses of patient visits primarily because more physicians will be competing for the same patient population. However, local economic factors and changing birth rates may also have an influence on the future pediatric practice. As a result, pediatricians may be forced to select a number of marketing strategies to maintain and increase their share of the patient population. Key marketing principals that may foster the growth of the pediatric practice have been considered by others,^{3,10-15} and some are briefly outlined below.

Location.—Knowing about the current population base near an office provides great insight into how to target services. For example, an expected population increase of children younger than 4 years in a specific geographic area in the next 5 years may provide support for adding a satellite facility. Additionally, as mentioned earlier, in the last 5 years, the greatest increase in

the number of US births has occurred in AAP districts IX and I. Demographic profiles in selected areas in these districts or in other areas of population growth may provide important information when considering relocating or starting a pediatric practice. Brown and Morley¹⁰ provide a list of places where such demographic information may be obtained.

Patient Satisfaction.—Data collected from an existing patient base may lead to a better understanding of how well patients feel about the services being offered. Courteous and timely treatment by staff, personal and warm relationship with the physician, quality medical information, use of educational materials considered valuable by patients, and comfortable physical surroundings are keystones for meeting patient's needs. A patient questionnaire that addresses these issues is probably one of the most important marketing tools.¹⁰ The information provided by a patient survey may not only measure patient satisfaction but also may define accurately a service area (How far will people drive to visit an office?).

Convenient Hours and Accessibility.—The single-parent family and families in which both parents work now predominate. The 9-to-5 office hours offered by many physicians may not conform to the schedule of the average patient. Evening and weekends office hours, and telephone accessibility, may attract patients who are concerned with convenient and professional services. Physicians who are more accessible to patients by making house calls, offering telephone consultation, and opening more offices may offer additional convenience to the existing or new patient.

New Patient Markets.—Increasing numbers of adolescents are seeking care from pediatricians. As Kappy⁴ has suggested "adjusting office hours to avoid mixing infants and adolescents, acquiring new skills to care for adolescents (eg, sports participation examinations, pelvic examinations, counseling, prescription of unfamiliar medications), addressing unique ethical issues, and facing economic problems in funding such care" represent new challenges and opportunities for the future pediatrician.

Becoming more involved in community activities may provide access to new

patients markets. Offering to speak about such topics as nutrition, sports-related injuries, drunk driving, and seat belt safety would represent a unique and effective approach to make personal and professional contact with civic and business organizations, Parent-Teacher Associations, and high schools.

In addition to the marketing techniques described above, several investigators¹⁰⁻¹⁶ have outlined other innovative techniques and strategies for developing and implementing an effective physician marketing plan.

COMMENT

Data presented herein provide an overview of the demography of office-based pediatricians, recent trends in patient population, and the present status of the pediatric market share. This study amplifies and updates previous investigations of the characteristics and future opportunities of practicing pediatricians.¹⁻⁴ It differs from other investigations because it centers on the current status of the pediatricians' market share of infants and children as determined from the latest nationally representative data. From this standpoint, only the report by Nadler and Evans² is comparable. However, Nadler and Evans describe market share data from 1964 to 1984 using information provided by Martinez⁹; details of methodology and a description of more recent data as described in the present report have not been published elsewhere.

The results presented herein show that four factors bear directly on the present and future status of the office-based pediatric practice: (1) the size of the office-based pediatrician population, (2) the size of the pediatric patient population, (3) the frequency of patient visits per office-based pediatrician, and (4) the size of the market share of the patient population. It seems that the rate of growth of the pediatrician population has outpaced increases in the birth rate of young children. As a result, the number of potential patients per pediatrician has undergone a net decline. Despite these changes in the pediatrician and patient populations, it is encouraging that the pediatricians' market share of young children has continued to grow. To date, pediatricians have realized more than 70% of the

market share of patients younger than 2 years.

It seems evident that the opportunity to expand the pediatricians' market share of young children may be limited. The pediatricians' share of young children may not grow fast enough to offset the increase in the population of pediatricians.

Growth of the pediatric practice may depend on providing more primary medical care to the adolescent population. The pediatricians' market share of children aged 10 to 19 years is growing and in 1987 the market share was 24%; the potential for continued growth exists. By defining the age limits of pediatrics, the Council on Child and Adolescent Health¹⁶ makes a strong case for changing the pediatricians' traditional focus on children under 10 years of age. The Council states that "the responsibility of pediatrics may begin with the fetus and continue through 21 years of age."¹⁶

Future growth of pediatrics may depend on the rate of growth of the pediatrician population. The Committee on

Pediatric Manpower¹⁷ offers several recommendations that are consistent with improving the quality of care available to children. Development of effective marketing strategies also may help increase the pediatricians' share of the patient population.

It is hoped that the information provided herein will be useful to health planners to ensure the continued growth of pediatrics and its high quality of care for children.

Linda Goode helped prepare the manuscript. Gene Roback provided the AMA estimate for the number of office-based pediatricians.

Risk Management Resources at Your Fingertips

Today, the challenge for physicians and health care institutions to maintain and improve the quality of care is greater than ever. The changing environment of medicine increasingly demands innovative responses from the profession. And, increasingly, physicians and institutions are responding.

The *Compendium of Patient Safety and Medical Risk Management Programs* is a comprehensive listing of patient safety/risk management resources available from the AMA/Specialty Society Medical Liability Project, the American Medical Association, the Council of Medical Specialty Societies, the Physician Insurers Association of America, national medical specialty organizations and state medical associations.

Featuring Capsule Program Descriptions and Complete Index

This is a one-of-a-kind compilation, a uniquely comprehensive guide to such resources as:

Guidelines and policy statements • Committee and task force activities • Courses and seminars • Self-assessment programs • Data banks • Research projects • Publications, from manuals and books to newsletters and pamphlets • Clearing-houses, resource centers, bibliographies • Videotapes, audiotapes, slide programs

Fredric Burg, MD, Philadelphia, Pa
Harold Levine, MPA, Galveston, Tex
Barbara Starfield, MD, Baltimore, Md
Larrie W. Greenberg, MD, Washington, DC

Purpose.—This department is intended to share information concerning educational efforts in the broad field of pediatrics. We welcome studies on the following topics: undergraduate and graduate education in medicine and allied health occupations; continuing education of health professionals; education of patients and families; and health education for the general public, the community, and organizations that contribute to the promotion and improvement of the health of children.

Editorial Comment.—*What kind of training do pediatric residents receive regarding head injuries? This study reports a survey of pediatric residency programs regarding whether such training took place, and also the type of training that was used. Apparently, we train adequately regarding acute management, but education about the long-term effects of head injuries is seldom provided. This important aspect is discussed herein.*—H.D.A.

Head Injury Training for Pediatric Residents

Janet S. Tyler, PhD; Mary P. Mira, PhD; Joseph G. Hollowell, MD, MPH

Annually, approximately 100 000 children under the age of 15 years suffer traumatic head injury severe enough to be hospitalized.¹ Advances in medical technology and trauma care are enabling more children to survive previously fatal head injuries. Therefore, pediatricians will be called on increasingly to treat and give advice regarding children who have survived traumatic head injuries.

Recently, professionals who treat children with head injuries have recommended that pediatricians become involved in the long-term follow-up of children with head injuries,² even when the injuries are only mild to moderate.³ This is an important recommendation because the majority of head injuries are classified as mild.⁴

This request for the careful monitoring of children with head injuries stems from recent evidence that even mild injuries may result in long-term physical sequelae, such as seizures⁵ and motor

impairments,⁶ as well as psychosocial and cognitive consequences.⁷ Research has indicated that approximately 25% to 30% of children with head injuries may require some form of special educational services.⁸

Because a pediatrician is believed to be the specialist who is best prepared to interpret medical data for school personnel,⁹ pediatricians will increasingly be called on to participate in interdisciplinary efforts,¹⁰ to collaborate with school personnel to serve children with disabilities,¹¹ and to give advice on the long-term rehabilitation of children with head injuries. Therefore, it is important to know what is available for training pediatricians in the area of head injuries. This article will report the results of a survey of pediatric residency training programs conducted to obtain information on the scope and depth of training in head injuries.

MATERIALS AND METHODS

In February 1988, a seven-page questionnaire booklet was mailed to the 227 directors of pediatric residency training programs in the continental United States. The names of the program directors and the addresses of the programs were obtained from the 1987 to 1988 edition of the *Directory of Residency Training Programs*.¹²

Ten days after the questionnaires were mailed, reminder postcards were mailed to all nonrespondents. In an effort to increase response rate, approximately 6 weeks after the initial mailing, duplicate questionnaires were sent to all nonrespondents.

The questionnaire asked about size and type of hospital and pediatric service. Pediatric training directors were asked to indicate from a list of topics relating to head injury which topics were covered during residency. They were also asked to indicate the format(s) for traumatic head injury training from the following format choices: (1) regularly scheduled conference or lecture, (2) problem case conference, (3) required readings, (4) random clinical exposure, or (5) planned clinical exposure.

Other survey questions included whether residents had rotations in the intensive care unit or neurology department, whether there was a formal evaluation of residents' knowledge of traumatic head injury, and who was responsible for providing pediatric rehabilitation care and follow-up.⁷

RESULTS

Responses were received from 110 (48%) of the 227 programs surveyed. Responders and the original sample were compared using directory data on the annual number of inpatient admissions. In the original sample 33% of the hospitals were considered small (<3000 inpatient admissions), 40% of the hospi-

tals were considered medium (3001 to 7000 inpatient admissions), and 27% were considered large (7001 to >10 000 inpatient admissions). Of those responding, 29% were from small hospitals, 42% were from medium-sized hospitals, and 29% were from large hospitals. Therefore, based on hospital size, the distribution of those responding was representative of the original sample. Thirty-three (30%) of the programs responding were located in a children's hospital.

Almost all of the programs (97%) responded that pediatric house officers rotate through an intensive care unit. For 98% of those respondents, the rotation was required. In 96% of the programs, pediatric house officers rotate through the neurology department (in 51% of the programs this was a required rotation). Long-term follow-up of pediatric patients with head injuries was a responsibility of the neurology service in 74% of the programs.

A formal evaluation of pediatric residents' knowledge of traumatic head injury occurred in 17% of the programs. The type of evaluation varied among hospitals (eg, written examination, clinical competence in head injury care and rehabilitation, or a combination of evaluation forms).

The responses of pediatric directors asked "In your hospital who is responsible for providing pediatric rehabilitation care?" are shown in Table 1. Rehabilitation medicine (42%) was the most frequently designated profession responsible for pediatric rehabilitation care. In 20%, general pediatrics was responsible for rehabilitation care, while a combination of services rather than one department was noted by 16% of the respondents. The remaining 22% of the respondents were divided among the following: medical specialties (eg, orthopedics, child development, trauma team), 5.5%; neurology, 4.6%; referred elsewhere, 4.6%; neurosurgery, 3.7%;

and no designated responsibility, 3.7%.

Head Injury Training

Table 2 shows the distribution of topic areas among programs providing planned exposure to each of the topics. The format random clinical exposure was not included in this tabulation.

Training topics reported by more than 50% of programs included emergency department trauma care of head injuries (89%), neurosurgical stabilization of head injuries (74%), and prevention of head injuries (66%). The topic covered by the fewest number of programs was the reentry of the child with a head injury to the school and community (28%).

The number of head injury topics covered varied greatly from no training in any topics listed to training in all of them. As an index of a program's overall intensity of head injury training, the total number of head injury topics covered was determined. For each program that offered planned training the number of different topics was summed and the most frequent number of head injury topics reported was three (19% of the programs covered three topics). It is interesting to note that in all cases where only one or two topics were covered, the topics dealt exclusively with prevention or some aspect of acute care. For those programs covering three topics (21 programs), 52 of the 63 topics also dealt with prevention or acute care of head injuries.

There was no apparent correlation between the size of the hospital program (annual number of inpatient admissions) and the extent of planned training offered pediatric residents, based on the number of topics covered. Furthermore, the analysis of the data did not point to any pattern of relationship between comprehensiveness of the training (ie, number of topics covered) and the service responsible for caring for these children.

COMMENT

The results of this survey indicated that scope and depth of training in head injury varied greatly among pediatric residency programs. It was shown that over 60% of the programs provided training in head injury prevention and acute care. However, approximately

half of the programs do not offer any planned training in head injury beyond the acute-care phase. Education regarding the long-term effects of traumatic head injuries or their management is extremely limited. Furthermore, only a limited number of programs formally evaluate their residents' knowledge of traumatic head injury.

Although training in the acute-care phase of head injuries is vital, that phase is a relatively short part of the injured child's life. The pediatrician often does not resume care of the child with a head injury until after the acute-care phase. Therefore, the pediatrician needs to be knowledgeable about the long-term effects of head injury so services can be provided and advice can be offered to parents and school personnel. Currently many pediatricians are not receiving any training in this area.

Our results indicate a lack of a systematic approach to the education of pediatric residents regarding head injuries. Ideally, such training should cover the full spectrum of issues faced by the injured child and family. Not only should issues beyond acute care be addressed through systematic training means (ie, planned clinical exposure, case conferences, etc), but also this broad spectrum of issues should be woven into the vehicles for care available in the existing training programs. For example, a site could be via the continuity clinics in which the resident provides primary care for the child with a head injury who is also being seen in other specialty clinics. Only a few patients would need to be seen for many aspects of rehabilitation to be presented. Building on the continuity process, prevention of head injuries and cognitive, academic, and family issues could be addressed. In the continuity process, when questions about the care of the injured child beyond the acute phase arise, residents have the resources of other professionals and the available

body of literature, thus increasing the breadth of the exposure.

There are also opportunities for this training within existing training formats. The intensive care unit and neurology rotations may be potential training sites for addressing long-term aspects of traumatic head injury. The majority of trainees have these rotations and in the majority of programs (74%) the neurology service offered long-term follow-up of pediatric head injuries.

Given the results of this survey, provision of services provided to children who have sustained traumatic head injuries may need to be reconsidered. Our data indicated that the medical specialty responsible for rehabilitation care varied among hospitals (with some programs reporting no one was responsible). In other words, there currently exists no standardized procedure for monitoring the long-term rehabilitation care of the child with a head injury.

Another important issue is that the acute-care specialist needs to be aware that the problems of head injury are not short-term, and to alert rehabilitation specialists early on so that planning for long-term rehabilitation may start during early recovery. Because the child's recovery will be long-term, it is important to establish as a routine the involvement of the full range of rehabilitation specialists early in the child's care. Therefore, early consultation would be considered an important part of head injury care. Ideally, consultations should begin while the child is still being cared for in the intensive care unit.

In summary, some important issues about head injury training need to be considered. First, with medical technology improving, more children will survive traumatic head injuries and return to school. Second, it has been established that traumatic head injury may cause long-term physical, cognitive, and behavioral sequelae. Third, parents

and school personnel are relying on pediatricians to guide them through the long-term recovery of the child's head injury. Therefore, pediatricians need to receive training in head injury beyond the acute-care stage. Pediatricians need to be knowledgeable about the long-term sequelae of head injury and to be aware that these children will need long-term rehabilitation and follow-up. While other studies are needed to define the knowledge base of residents in head injury, this study has shown that many residents are not receiving training in this important area.

This study was supported in part by Title VI-B grant 8805-FY88 from the Kansas State Department of Education, Topeka, Kan, and federal government grants MCJ-000944 from the Department of Health and Human Services, Rockville, Md, and ADD-07DD0262-17 from the Administration on Developmental Disabilities, Department of Health and Human Services, Washington, DC.

MONO-VACC® TEST (O.T.) (TUBERCULIN, OLD)

(TUBERCULIN, OLD)
MONO-VACC® TEST (O.T.)

BRIEF SUMMARY

INDICATIONS

Screening for tuberculosis. Positive reactions should be confirmed by Mantoux method and possibly other diagnostic test procedures.

CONTRAINDICATIONS

None when test is used as directed.

WARNINGS

Although anaphylactic reactions have not been reported with Mono-Vacc, this remote possibility should be considered and epinephrine should be available.

PRECAUTIONS

Do not apply Mono-Vacc to acneiform skin, hairy areas or where there is inadequate subcutaneous tissue. Although repeated testing of uninfected individuals does not sensitize to tuberculin, it may have a "booster" effect in persons with low levels of sensitivity to homologous or heterologous mycobacterial antigens. Testing should be done with caution in persons with active tuberculosis, however, activation of quiescent lesions is rare. Tuberculin color variation may occur between different lots without alteration of potency or stability. Discard each Mono-Vacc test after use. DO NOT REUSE.

Drug Interactions:

The administration of adrenal corticosteroids or immunosuppressive drugs may decrease the intensity of or prevent a tuberculin reaction. Tuberculin sensitivity may decrease or disappear temporarily as a result of febrile illness; measles and other exanthemas; live virus vaccination; sarcoidosis and miliary or pulmonary tuberculosis.

Pregnancy Category C. Tuberculin, Old:

Animal reproduction studies have not been conducted with Tuberculin, Old (Mono-Vacc Liquid Tuberculin Test, O.T.). It is also not known whether Tuberculin, Old can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Tuberculin, Old should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

Vesiculation, ulceration, or necrosis may occur in highly sensitive subjects at the test site. Pain or pruritus at the test site may be relieved by topical glucocorticoid ointment or ice packs.

RE-INTRODUCE THE OLDEST ADVANCE IN MEDICINES.

It's called talking. If your older patients don't ask you about the prescriptions they've been given, make it a point to tell them what they need to know. Make sure they know the medicine's name, how and when to take it, precautions, and possible side effects. Encourage them to write down the information and ask you questions about things they don't understand.

You'll also want to take a complete medication history including both prescription *and* non-prescription medicines. The history can alert you to the potential for drug interactions and help you simplify their regimen.

Re-introduce the oldest advance in medicines. Make talking a crucial part of your practice. Because good, clear communication about medicines isn't a thing of the past. It's the way to a healthier future.

*Before they take it,
talk about it.*

Book Review

Textbook of Pediatric Emergency Medicine, 2nd ed, edited by G. Fleisher and S. Ludwig, 1388 pp, \$112.50, Baltimore, Md, Williams & Wilkins, 1988.

Fleisher and Ludwig have taken on an Olympian task. In the *Textbook of Pediatric Emergency Medicine*, the editors have attempted to provide a single informative source of the pathophysiology, differential diagnosis, and acute management of practically all pediatric conditions that the emergency department practitioner will encounter. They have done a superb job.

The book is divided into six sections. The first is devoted to life-support emergencies, the hallmark of emergency department practice. The second section, titled "Signs and Symptoms," includes the pathophysiology, differential diagnosis, and essential aspects of clinical evaluation for specific complaints that bring children to the emergency department. The third, fourth, and fifth sections, titled "Medical Emergencies," "Surgical Emergencies," and "Psychosocial and Medicolegal Emergencies," respectively, focus in more detail on most of the conditions identified in section 2. The final section illustrates 55 procedures frequently performed in caring for children in the emergency department. Helpful appendixes provide information on pediatric resuscitation equipment for use in the emergency department, office, or clinic, and a list of pediatric resuscitation drugs.

This book is a second edition. Nearly all chapters have been rewritten with new tables, algorithms, and illustrative roentgenograms. In the "Signs and Symptoms" section, tables of both common and life-threatening causes have been added. There are new, well-written chapters on important topics such as apnea, heart murmurs, the septic-appearing infant, sore throat, visual disturbances, and wheezing. Other new chapters cover neonatal resuscitation, the approach to trauma, metabolic emergencies, bites and stings, radiation injuries, and pulmonary emergencies. The chapter on jaundice has been enhanced by being divided into two chapters on conjugated and unconjugated hyperbilirubinemia.

Because of the rapid growth of medical knowledge, many textbooks are out of date by the time they are published. Fortunately, this book has largely avoided that pitfall: the newer cephalosporins, with dosing recommendations, have been included, and pulse oximetry is mentioned as a monitoring aid. The resuscitation section includes a good discussion on the limits of bicarbonate therapy, the use of "quick-look" paddles for determination of cardiac rhythm, and the intracosseous infusion technique. New management algorithms for asystole, bradycardia, ventricular fibrillation, and electromechanical dissociation are presented.

One cannot expect a text that explores an immense, rapidly growing field to be perfect, and there are a few problems worth noting. Although the book covers most of the clinical conditions encountered, it omits a thorough discussion of the management of children with human immunodeficiency virus infection. The emergency department is the most likely place these children present, and

their problems are unusual enough to deserve special mention. On the one hand, certain presenting complaints may suggest the possibility of human immunodeficiency virus infection long before "classic" or textbook conditions associated with the acquired immunodeficiency syndrome have manifested themselves. Alternatively, the child with human immunodeficiency virus infection who has a common complaint (such as fever) may require a different evaluation and disposition from that of the healthy child with a similar complaint.

Other problems occur in the area of management recommendations. Epinephrine, susphrine, and theophylline are described as the mainstays of asthma therapy. In many emergency departments, the use of β -agonists has made susphrine obsolete. Use of metered-dose inhalers is gaining popularity as first-line therapy for discharged asthmatics, particularly with the development of newly designed adjunctive devices that facilitate their use by younger children. Susphrine and theophylline are also recommended for infants with bronchiolitis who respond to epinephrine therapy. We have noted several cases of theophylline toxicity in young infants treated with theophylline for bronchiolitis; thus, we almost never use it on an outpatient basis in infants less than 6 months of age.

Consideration of chlamydial infection in children being evaluated for either sexual abuse or gonorrheal infection is not discussed, although concern for this clinical problem is increasing in many emergency departments.

Finally, a detailed management algorithm for children with suspected epiglottitis would have been helpful, serving as a model for institutions that do not already have a protocol in place for dealing with this fulminant infection. Directing the practitioner to place an intravenous line in the "cooperative" patient with epiglottitis suggests that it is an acceptable practice to restrain the child or insist that she or he lie down. Moreover, the insistence on a lateral neck roentgenogram could cause unnecessary delay in securing an adequate airway. I don't consider it desirable to obtain the lateral neck roentgenogram in the child with probable epiglottitis (although many physicians will obtain one). Instead, I consider it to be most helpful in those situations where the primary diagnosis is croup but the possibility of epiglottitis hasn't been ruled out.

To focus on this book's few problems, however, is really unfair. It's a bit like criticizing an Olympic gold medalist for not simultaneously breaking the world record. In this new edition of *Textbook of Pediatric Emergency Medicine*, Fleisher and Ludwig have tackled an Olympian task and have come through with flying colors. Their book is a major achievement for which emergency department practitioners will be extremely grateful.

ALCOHOL IS NOT FOR UNBORN BABIES

Having a baby is a time to take special care of yourself. When you're pregnant, everything you eat and drink affects the child you are carrying.

Drinking beer, wine or liquor may hurt your baby. Heavy drinking can result in serious permanent mental and physical birth defects.

Alcohol is not something to be taken lightly during pregnancy. For baby's sake... and yours... the safest choice is not to drink during pregnancy.

For more information, write the National Clearinghouse for Alcohol Information, Box 2345, Rockville, MD 20852.

HOUSE BASED PEDIATRICIANS (HBPs)

Huntington Memorial Hospital of Pasadena, California, a major affiliate of the University of Southern California School of Medicine, is seeking to hire four board eligible/certified pediatricians by July 1, 1989 to cover its 34-bed pediatric floor. These four house-based pediatricians (HBPs) will provide in-house coverage that traditionally would have been provided by pediatric interns or residents.

Founded in 1892, Huntington Memorial Hospital is a 606-bed non-profit medical center that serves the communities of the San Gabriel Valley of Los Angeles County. The total service area population of the San Gabriel Valley is approximately two million people. The Hospital offers a tertiary Infertility Center, Perinatal High-Risk Unit, a Neonatal ICU and renowned ECMO Center, a comprehensive Pediatric Center and a Pediatric ICU.

The compensation is competitive with the HMOs or other salaried positions in the area: \$70,000 annual salary; health insurance (medical, dental, vision); life insurance (\$50,000 term life); accidental death & dismemberment (\$50,000); paid 3-week vacation; and a \$1000 annual CME fund.

Those interested should send their CV and inquiries to Edgardo L. Arcinue, M.D., Head, Department of Pediatrics, 100 Congress Street, Pasadena, CA 91105; (818) 397-8688.

PEDIATRICIAN

Immediate opportunity to associate with five pediatricians in an accredited 70-doctor multispecialty group. Drawing area of 400,000. Modern hospital within five minutes of Clinic. Stimulating Big-10 university community of 110,000 with superb cultural advantages. Ideal for families. Medical school teaching affiliation if desired. Excellent initial guarantee and fringes with early associate status, subsequent income based exclusively on productivity. Subspecialty training in allergy desirable. Send CV to:

Clinical and Bacteriologic Features of Chronic Sinusitis in Children

David G. Tinkelman, MD, Howard J. Silk, MD

• The clinical and bacteriologic aspects of chronic sinusitis in childhood were studied. Of 35 children who underwent surgical procedures for chronic sinusitis, 22 had positive bacteriologic cultures of aspirates from the sinus. The most common organisms isolated were *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Branhamella catarrhalis*. Five of eight *S pneumoniae* strains were relatively resistant to penicillin and resistant to sulfamethoxazole-trimethoprim. All of the *B catarrhalis* and 20% of the *H influenzae* organisms were β -lactamase positive. Overall, 14 of 28 of the bacteria were penicillin resistant. In addition, all 12 children 2 years of age or younger had a positive bacterial culture as compared with much lower rates in older children. Although the incidence of *S pneumoniae* strains that are relatively resistant seems to be rising, to our knowledge we report the first description of these organisms as significant pathogens in chronic childhood sinusitis. These results indicate that chronic, difficult to manage sinusitis in very young children is frequently bacterial in origin, especially if the patient is 2 years old or younger. In light of the frequent failure of antibiotic therapy and considering the incidence of relatively resistant *S pneumoniae* strains, puncture of the sinus should be considered early in the course of chronic sinusitis to isolate pathogenic organisms and determine appropriate antimicrobial therapy.

(AJDC. 1989;143:938-941)

During the past several years, sinusitis has been increasingly recognized in childhood. The studies of Wald

Unlike the predominant organisms in acute sinusitis, which include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Branhamella catarrhalis*,¹ chronic sinusitis may yield anaerobic isolates.⁴ Despite multiple courses of antibiotics, chronic sinusitis is often unremitting, and patients frequently require referral to an otolaryngologist for surgical management. We undertook this study to evaluate the clinical and bacteriologic findings of chronic sinusitis in a group of children who underwent surgical procedures for this condition.

PATIENTS AND METHODS

The records of 116 consecutive children who underwent surgical procedures for chronic sinusitis at four metropolitan Atlanta, Ga, hospitals during a 12-month period were reviewed. Charts were considered to be complete if they contained all of the following: complete medical records, including sinus roentgenograms, aerobic and anaerobic cultures of sinus aspirates, antibiotic sensitivities, and complete records of antimicrobial therapy. Of the 116 patients, 77 were excluded from evaluation as culture and sensitivity results were not obtained, and 4 were excluded due to lack of sinus roentgenograms. Therefore, 35 patients were considered eligible for evaluation.

Clinical signs and symptoms of chronic sinusitis included purulent nasal discharge, cough (often nocturnal), facial pain or swelling, sore throat, or headache that were present for greater than 30 days.

Sinus roentgenograms (anteroposterior, occipitontental, and lateral views) were obtained in all patients and were reviewed by a radiologist at the time of presentation. The roentgenograms were interpreted either as normal or abnormal based on evidence of opacification, air-fluid levels, or a mucosal thickening of 5 mm or greater.¹

If there was no clinical improvement after therapy with antimicrobial agents and antihistamines or decongestants, patients were considered treatment failures and were con-

sidered candidates for surgical intervention. Treatment courses with antibiotics ranged from 10 to 21 days each.

Surgery was performed at one of four metropolitan Atlanta hospitals. All patients underwent irrigation and drainage of the maxillary sinuses; nasoastral windows were placed and adenoidectomy was performed as deemed appropriate by the individual otolaryngologist.

Sinus aspirates were obtained after swabbing of the nasal mucosa with povidone-iodine solution, which was allowed to dry. The nasal wall was punctured in the area of the inferior turbinate, and the sinus was aspirated. If no secretions were obtained, the sinus was irrigated with 1 to 3 mL of nonbacteriostatic saline and reaspirated. Air was evacuated from the syringe. The needle was removed, and the syringe was capped and transported to the microbiology laboratory where samples were plated within 30 minutes of collection.

Sinus aspirates were plated onto chocolate agar for aerobic culture and were plated onto prereduced anaerobic blood agar with kanamycin sulfate and vancomycin hydrochloride for anaerobic growth. Three anaerobic plates were incubated in anaerobic jars and examined at 48 and 96 hours. Bacterial isolates were identified by standard methods⁵ and were considered significant if at least 10⁴ colony-forming units per milliliter were recovered.¹ Isolates were screened for penicillin sensitivity by the disk diffusion method using 1- μ g oxacillin sodium disks on commercial agar (Mueller-Hinton) plus 5% sheep's blood.⁶ Strains that showed an inhibition zone of 20 mm or less on the 1- μ g oxacillin disk were considered relatively resistant to penicillin.^{6,7} Strains of *H influenzae* and *B catarrhalis* that were resistant to ampicillin were tested for β -lactamase production.⁸ Antibiotic sensitivities were otherwise determined by the Kirby-Bauer method.⁹

RESULTS

The medical records of 35 children were eligible for entry into the study. Males outnumbered females 26 to 9. The children ranged in age from 10 months to 16 years (mean \pm SD, 4.9 \pm 3.9 years).

Symptoms and Treatment

The preponderant symptoms in these patients were purulent rhinorrhea, postnasal drip, or both occurring in 27. Fourteen patients had a cough, often nocturnal, another 3 children had episodes of wheezing, and 10 children had both drainage and coughing. All 35 children had roentgenographic evidence of sinusitis, 32 of 35 had complete opacification of at least one maxillary sinus, and the remaining 3 children had substantial mucosal thickening of 5 mm or greater. Four patients had pansinusitis. Isolated frontal sinus disease was not found. Eleven patients had a history and physical examination results compatible with allergic rhinitis. The IgE levels and immunoglobulin values were not available for all patients.

All children were receiving antimicrobials at the time of their surgical procedures. Thirty children had at least two previous courses of different antibi-

otics, 14 had three courses, 7 had four different antibiotics, and 1 child received five different antibiotics. The most commonly used antibiotics, listed in order of decreasing frequency, were as follows: cefaclor, amoxicillin, sulfamethoxazole-trimethoprim, amoxicillin-clavulanate, potassium, erythromycin ethylsuccinate, cephalexin, and doxycycline hyclate. The number of antibiotic courses before obtaining cultures did not correlate with bacteriologic recovery. Each antibiotic was used for 10 to 21 days at a time.

All patients had irrigation and drainage of their maxillary sinuses, 29 children also underwent placement of antral windows, and 10 patients underwent adenoidectomy as well. There were no surgical complications. Twenty-two of 35 families reported clinical improvement following the procedure, and 13 reported no change.

Bacteriologic Findings

In this cohort, 28 bacterial isolates were recovered from 22 of 35 patients (Table 1). Nontypeable *H influenzae* and *S pneumoniae* were cultured most frequently (8 patients each), followed by *B catarrhalis* (4 patients), *S aureus* (3 patients), group A *Streptococcus* (3 patients), *Staphylococcus warneri* (1 patient), and *Streptococcus sanguis* (1 patient). Two different organisms were recovered from 4 children, and 1 child had 3 bacterial species recovered. Two of the 8 *H influenzae* isolates and all 4 *B catarrhalis* isolates were β -lactamase positive. No anaerobic organisms were recovered. Five of the 8 strains of *S pneumoniae* isolated were relatively resistant to penicillin, with less than 12 mm of diffusion on 1- μ g oxacillin disks. All 5 were also resistant to sulfamethoxazole-trimethoprim; in 1 patient

the strain was resistant to gentamicin sulfate as well. All were sensitive to second- and third-generation cephalosporins, clindamycin hydrochloride, vancomycin, and chloramphenicol. Sensitivities to amoxicillin-clavulanate were not obtained (Table 2). Three of the patients with *S pneumoniae* strains relatively resistant to penicillin also had β -lactamase-negative *H influenzae* recovered from their sinuses; 1 patient had *B catarrhalis* recovered. All 5 children with relatively resistant *S pneumoniae* strains had received a β -lactam drug before surgery and were younger than 3 years old. Overall, 14 of 28 of the isolates were resistant to the penicillins.

There was a strong positive correlation between age and positive bacterial cultures. All 12 children who were 2 years of age or younger had a positive culture compared with 7 of 12 children between 2 and 5 years of age and one fourth of the patients older than 10 years (Table 3). The number of preoperative antibiotics did not differ between age groups and did not correlate with culture results.

COMMENT

Although acute sinusitis in children has become a well-recognized clinical problem,^{1,4} there remains a scarcity of data concerning chronic childhood sinusitis.

In this group of children with chronic sinusitis, 22 of 35 had bacteria isolated from their paranasal sinuses compared with approximately 75% of children with acute sinusitis as reported in the literature.¹ The bacteriologic characteristics of chronic sinusitis in this patient population are similar to those of acute infection, with *H influenzae*, *S pneumoniae*, and *B catarrhalis* being recovered most frequently. A study by

Brook⁴ isolated anaerobic bacteria in 37 of 40 children with chronic sinusitis. The results of our study could not confirm the prevalence of anaerobes as significant pathogens. However, differences in laboratory technique and antibiotic use at the time of surgery may have resulted in the lack of anaerobic recovery. Our patient population was also significantly younger than that of Brook⁴ (mean, 4.9 vs 11 years), whose patients were all older than 6 years. This age differential may also account for the differences seen in the bacteriologic characteristics of chronic sinusitis. Preliminary data from Rachelefsky et al¹⁰ isolated only one anaerobe from eight children with chronic sinusitis. Anaerobic organisms, therefore, may not play as large a role in chronic childhood sinusitis as previously thought.

All 12 children 2 years old or younger had positive sinus cultures as compared with 22 of 35 children overall. This correlation was striking and, to our knowledge, has not been previously reported. Age was the only variable that correlated with a positive culture; clinical symptoms, white blood cell counts, and type and frequency of antibiotic therapy were not associated with a positive result. Predisposing factors for sinusitis in children include obstruction of the sinus ostium secondary to upper respiratory tract infections, allergy, nasal polyps, immotile-cilia syndrome, immunodeficiency syndromes, and foreign bodies. In particular, the role of viral upper respiratory tract infections, allergy, and immune dysfunction may contribute to the high recovery rate of bacteria in those younger than 2 years. Immunoglobulin levels and atopic status were not determined for the majority of our patients, and therefore we cannot draw any conclusions as to whether these factors played a role in the age-associated culture results.

The recovery of relatively resistant *S*

pneumoniae strains from five patients was of great interest. Prevalence rates of these strains may range as high as 3% to 16%^{11,12} in the pediatric population, with nasopharyngeal carriage rates of 14% to 49%¹³ in selected geographic populations. While episodes of pneumonia, meningitis, bacteremia, and otitis media due to relatively resistant *S pneumoniae* strains have been reported,^{14,15} to our knowledge this is the first demonstration of the entity in association with chronic sinusitis in children.

Because of the retrospective nature of this study, the relatively resistant strains of *S pneumoniae* were not available for minimum inhibitory concentrations to be obtained. Although the minimum inhibitory concentration is the definitive method for determining penicillin resistance, all five pneumococcal strains had inhibition zones of 12 mm or less on 1- μ g oxacillin disks, which is considered to be a highly selective screening method for determining resistance to penicillin, although it cannot distinguish between true penicillin resistance and relative penicillin resistance.¹³ We cannot conclusively state that these were truly penicillin-resistant strains of *S pneumoniae*, and, therefore, are considering them to be relatively resistant.

Pneumococci also seem to be increasingly resistant to sulfamethoxazole-trimethoprim,^{13,16} and all five strains relatively resistant to penicillin were resistant to sulfamethoxazole-trimethoprim as well. As previously documented,^{14,15} all of the children in this cohort with strains relatively resistant to penicillin were younger than 3 years and had been treated with a β -lactam drug; four of five patients had also received sulfamethoxazole-trimethoprim. Thus, previous therapy with a β -lactam antibiotic or sulfamethoxazole-trimethoprim presumably selects for the relatively resistant pneumococci, particularly in areas such as the paranasal sinuses, where there is relatively poor penetration of the penicillin antibiotics.^{17,18} Age also seems to be a risk factor for infection with strains relatively resistant to penicillin, possibly caused by the increased rate of pneumococcal infection in young children as well as their relative inability to mount a humoral response to polysaccharide antigens.

Retrospective studies have limitations. The exclusion of 77 of 116 patients from this study was necessary since culture and sensitivities were not obtained on the sinus aspirates. However, the 35 patients studied do not differ in age or clinical symptoms from those excluded. Although the sample size is small, it is similar to that of other studies of childhood sinusitis.¹⁴ Nevertheless, these data must be considered preliminary, with prospective follow-up studies necessary for confirmation.

Because of the differences in antibiotic sensitivities between different strains of relatively resistant *S pneumoniae* and the preliminary nature of our data, one needs to be cautious with therapeutic recommendations. Cefaclor has been shown to be less effective than other cephalosporins for use against these strains,¹⁶ which is supported by our study, in which cefaclor was the most widely prescribed antibiotic, although it did not seem to alter the bacteriologic recovery of relatively resistant strains of *S pneumoniae* or to change the clinical findings. Other cephalosporins such as cefuroxime or ceftriaxone sodium may be more effective in eradicating these infections,¹⁶ and our data support this as well (Table 2). As penicillin resistance in pneumococci is caused by alterations in penicillin-binding proteins¹⁹ rather than β -lactamase activity, treatment with amoxicillin-clavulanate potassium would not seem to be an effective antimicrobial for relatively resistant strains, although sensitivities were not obtained to confirm this theory. Other alternate antibiotics may include erythromycin, chloramphenicol palmitate, and vancomycin.

The standard course of therapy for sinusitis is 10 to 14 days, although some authors now recommend a 21- to 28-day course. The beneficial use of antihistamines and decongestants has also not been sufficiently documented.

In light of the increasing incidence of relatively resistant strains of *S pneumoniae* and the high rate of bacteriologic recovery in young children with chronic sinusitis, these preliminary data indicate that diagnostic sinus puncture should be considered early in the course of chronic sinusitis to isolate pathogenic organisms and to select appropriate antimicrobial therapy. Pro-

spective studies are needed to investigate this issue further, as well as the role of allergy and possible immune dysfunction in children with chronic sinus disease.

We thank Ramon Franco, MD, Wiley Parker, MD, and Ramie Tritt, MD, for giving us access to their patient records. Mandy Carroll helped with data collection and entry.

Sex Steroids Do Not Influence Somatic Growth in Childhood

Susana P. Campos, MD, Margaret H. MacGillivray, MD

• The influence of sex steroids on somatic growth during childhood was evaluated by reviewing linear growth characteristics of 18 agonadal patients with normal sex chromosomes. None of the heights throughout childhood and before the onset of sex steroid therapy were below 2 SDs of the mean. Based on the normal z scores of these patients, we concluded that somatic growth throughout the childhood and prepubertal years is not sex-steroid dependent.

(AJDC. 1989;143:942-943)

Previous studies have evaluated the growth-promoting effects of androgens, estrogens, and/or growth hormone treatment in girls with Turner syndrome. Recently, the efficacy of low doses of estradiol was assessed in patients with Turner syndrome who were as young as 5 years of age.¹ Estrogen treatment of these young girls was based on clinical observations that linked the growth spurt of girls with normal karyotype to small increments in estrogen production during early puberty and to the assumption that estrogen deficiency in girls with Turner syndrome might play a role in their growth deceleration during childhood.

We examined the influence of sex steroids on somatic growth during childhood by evaluating the linear growth characteristics of 18 anatomically or functionally agonadal patients with normal sex chromosomes. Based on their growth patterns, we concluded that somatic growth throughout the childhood and prepubertal years is not dependent on gonadal estrogens or androgens.

PATIENTS AND METHODS

The linear growth charts of 18 anatomically or functionally agonadal patients with structurally normal sex chromosomes were reviewed. Each patient's assigned sex, clinical diagnosis, karyotype, age at laparotomy and/or gonadectomy, gonadotropin levels, age, and height in SD scores (z scores) at the

onset of sex steroid replacement are given in the Table. The various causes of agonadism included gonadal agenesis, gonadal dysgenesis, vanishing testes syndrome, surgical gonadectomy in infancy for intersex problems, gonadal destruction from radiation and chemotherapy for primary malignancy, and biosynthetic defect in sex steroid production (17 α -hydroxylase deficiency). The agonadal state was confirmed in infancy and early childhood by exploratory laparotomy, low plasma sex steroid concentrations, and/or elevated plasma gonadotropin levels.

In four patients (patients 3, 5, 9, and 12), the agonadal state was confirmed after surgical exploration at a relatively advanced age (15 years 7 months, 15 years 3 months, 14 years 6 months, and 10 years, respectively). Patient 3 was referred at age 13 years for delayed adolescence. The plasma follicle-stimulating hormone (FSH) level exceeded 50 IU/L (normal, <10 IU/L). Plasma luteinizing hormone (LH) level was 25.1 IU/L (normal, 2 to 6 IU/L), and her vaginal smear showed no estrogen effect. Streak gonads were removed at the time of laparotomy. Patient 5 was first seen at age 15 years 6 months for delayed sexual development. The plasma gonadotropin level was elevated (FSH, 47.7 IU/L; LH, 12.9 IU/L), and there was no estrogen effect on vaginal smear. On laparoscopy, one gonad was absent and the other was atrophic. Patient 9 was evaluated at 8 months of age for micropenis and small, soft, retractile testes. He was not available for follow-up and returned at age 14 years 10 months after having undergone bilateral inguinal exploration, bilateral orchidopexy, and insertion of testicular prostheses. Histopathologic evaluation revealed atrophic testes. Plasma FSH level was less than 1.0 IU/L, LH level was 6.6 IU/L, and testosterone level was 1.6 nmol/L (normal adult male level, 140 to 280 nmol/L). A gonadotropin-releasing hormone test revealed gonadotropin deficiency. Patient 12 presented at age 15 years 1 month with micropenis and undescended testes. He had undergone abdominal and inguinal exploration at age 10 years and no gonads were found. Plasma FSH level was 46 IU/L, plasma LH level was 21.0 IU/L, and serum testosterone level was 0.8 nmol/L.

Patients 4 and 9 were unusual in that they had atrophic testes and severe gonadotropin deficiency. Patient 4 had severe micropenis with palpable erectile tissue being only 4 to 5 mm. She underwent bilateral gonadectomy and female sex reassignment at age 1 year 3 months. The plasma FSH level was 2.0 IU/L and LH level was 1.0 IU/L before sex steroid

replacement. Patient 9 was discussed previously. They are included in this study because they had nonfunctional gonads and absence of sex steroids. They are not representative of the usual patients with gonadotropin deficiency whose testes are responsive to gonadotropin replacement.

Twelve patients were raised as females: seven of these had a 46,XY karyotype and five had a normal 46,XX karyotype. Absence of sex steroids in these patients was confirmed by either low plasma estradiol level (<73.4 pmol/L) and/or absence of estrogen effect on vaginal mucosal smears. The six phenotypic males all had a normal 46,XY karyotype and low plasma testosterone levels (0.4 to 1.6 nmol/L) associated with either documented vanishing testes syndrome or atrophic testes. Five of the patients (patients 1, 2, 12, 15, and 18) had the syndrome of vanishing testes. All these individuals had a small but normally formed penis and empty scrotal sacs. Elevated gonadotropin levels and very low gonadal steroids were measured before replacement treatment, making a human chorionic gonadotropin stimulation test unnecessary. Nevertheless, patients 2, 15, and 18 had had a human chorionic gonadotropin stimulation test done, which showed no rise in plasma testosterone level.

The age range at onset of sex steroid replacement was 11 years 5 months to 15 years 8 months; none of the patients had received sex steroid treatment before starting replacement therapy. We chose to evaluate the growth of our patients on the basis of their sex of rearing because somatic growth during childhood does not appear to be dependent on genetic sex; the Figure illustrates that the growth curves of boys and girls are almost identical during this period.

RESULTS

None of the 18 patients had heights and growth percentiles that were below 2 SDs of the mean for normal children (Figure). The z scores at initiation of sex steroid therapy ranged from -1.22 to 2.06 (Table). Sex steroid replacement was begun at a chronologic age compatible with normal puberty and resulted in the expected physiologic growth spurt (Figure). Historical information on parental heights was available in 7 of 11 adult patients. The final adult heights of these patients closely approximated or exceeded the midparental height.

†Normal follicle-stimulating hormone (FSH) level is less than 10 IU/L and normal luteinizing hormone (LH) level is 2 to 6 IU/L.

COMMENT

The normal linear growth patterns observed in our agonadal children suggest that gonadal steroids do not influence somatic growth during childhood. Although the agonadal state was documented at a relatively advanced stage in four of the patients (patients 3, 5, 9, and 12), the pathologic examination of their gonads indicated that they had congenitally nonfunctional gonads. Two of the patients (patients 10 and 11) had a total lack of gonadal steroids due to a congenital 17 α -hydroxylase deficiency. The remainder of the patients had gonadectomy performed in their early childhood years.

All 5 patients who were started on sex steroid therapy at 15 years of age or later had a slightly negative z score. Only 3 of the 13 remaining patients in whom steroid therapy was initiated between ages 11 to 13 years had negative z scores. Although it appears that age at initiation of sex steroid therapy influences the z score, no patient regardless of the age of onset of sex steroid replacement had a z score that was below 2 SDs of the mean.

Based on these observations, it is highly unlikely that estrogen defi-

All available heights of phenotypic male and female patients plotted on the normal growth percentiles (5th, 50th, 95th) for male and female patients.

ciency is responsible for the childhood growth failure of girls with Turner syndrome. More likely, loss of growth-regulating genes on the short arm of the X chromosome (Xp) and possibly an in-born difference in skeletal growth are etiologic factors.

Estrogen treatment in girls with Turner syndrome has been initiated at an increasingly young age.^{1,2} Previous studies suggest that the growth-promoting effects of estrogen therapy in Turner syndrome are not sustained beyond 12 to 24 months,^{3,4} and long-term adverse effects of estrogen on bone maturation and adult height have been reported in these patients.⁵ Since sex steroids do not play a role in somatic growth during the first decade of life, we recommend that estrogen treatment of girls with Turner syndrome be initiated at a chronological age that is compatible with onset of normal puberty.

Increased Phagocytic Cell Chemiluminescence in Patients With Cystic Fibrosis

Robert L. Roberts, MD, PhD, E. Richard Stiehm, MD

• The oxidative burst of polymorphonuclear cells and monocytes from patients with cystic fibrosis as measured by luminol-enhanced chemiluminescence was examined after *in vitro* activation of the cells. All patients were outpatients at the time of the assays; their median age was 25.5 years (range, 12 to 33 years) and normal controls were young healthy adults. Stimulation of polymorphonuclear cells with phorbol myristate acetate, the chemotactic peptide *N*-formyl-methionyl-leucyl-phenylalanine, and the calcium ionophore A23187 resulted in significantly greater chemiluminescence responses from the cells of patients than from the control cells. The monocyte response of patients to opsonized zymosan was also greater than that of controls. Thus, phagocytic cells from adolescents and young adults with cystic fibrosis have a greater chemiluminescence response to a variety of stimuli. This may result in tissue damage in the lungs of these patients and thus make them more susceptible to pulmonary infections.

(AJDC. 1989;143:944-950)

Pulmonary infections account for the majority of deaths in cystic fibrosis (CF), but patients with CF have little difficulty containing infections outside the respiratory tract. The ability to mount normal systemic immune responses suggests that the respiratory host defense mechanisms of patients with CF may be defective, evidenced by continued colonization of bacteria in the lungs despite antibiotic therapy.

Phagocytic cells, alveolar macrophages, and polymorphonuclear leukocytes (PMNs) in the normal lung are

able to prevent the colonization of bacteria that enter the lower airways. These phagocytic cells are present in large numbers in the lungs of patients with CF,¹ thus making a chemotactic defect an unlikely cause for their increased susceptibility. After the bacteria have been opsonized and ingested, they are killed by the release into the phagolysosome of reactive oxygen intermediates (ROIs), proteolytic enzymes, and other antimicrobial agents from the phagocyte. These ROIs and proteolytic enzymes from the phagocyte may also injure host tissues, which has been documented to occur in adult respiratory distress syndrome²⁻⁵ and in experimental models of inflammatory lung disease.⁶⁻⁸

Fick et al^{9,10} have shown that immunoglobulins specific for *Pseudomonas aeruginosa* are present in the bronchoalveolar lavage fluid of patients with CF. However, up to 80% of the IgG *Pseudomonas* antibody in the bronchoalveolar lavage of patients with CF had been degraded into Fab and Fc fragments, which inhibit phagocytosis of the bacteria by pulmonary alveolar macrophages. Fragmentation of immunoglobulin molecules may be promoted by the release of proteolytic enzymes and ROIs from phagocytic cells.¹¹⁻¹³ Thus, increased phagocytic cell activity in the lungs may damage protective antibodies and allow bacterial colonization to occur.

In the present study, PMNs and monocytes from patients with CF were studied for their ability to release ROIs as measured by chemiluminescence. The effects of extracellular calcium on these responses were also examined. The phagocytic cells of patients with CF were found to have significantly increased chemiluminescence activity for all stimuli tested compared with age-matched controls in the presence or absence of extracellular calcium. The excessive release of ROIs from the

phagocytic cells of patients with CF may impair local host defenses in the lungs and result in pulmonary infections.

MATERIALS AND METHODS

Patient Population

Patients with CF were identified from among the outpatient population treated at the Cystic Fibrosis Center at UCLA in accordance with the University of California Human Subjects Protection Committee. The majority of the patients treated at this clinic are older adolescents and young adults. The total study population had a median age of 25.5 years and a mean age (\pm SEM) of 23.6 ± 1.3 years with a range of 12 to 33 years. All patients had positive sputum cultures for *P. aeruginosa* and the results of their pulmonary function tests, complete blood cell counts, and erythrocyte sedimentation rates were recorded. Most of the patients were receiving some form of oral or inhaled antibiotic at the time of the assay. Patients who were severely ill and who required hospitalization were not included in the study population. Normal volunteers were in good health and had an age range of 21 to 38 years.

Materials

All reagents were obtained from Sigma Chemical Co, St Louis, Mo, except for polyvinylpyrrolidone-treated silica (Percoll, Pharmacia Fine Chemicals, Piscataway, NJ) and 5-amino 2,3 dihydro 1,4 phthalazinedione (luminol, Eastman Kodak, Rochester, NY).

All water-insoluble compounds were dissolved in dimethyl sulfoxide to make appropriate stock solutions so that the final concentration of dimethyl sulfoxide in the reaction mixtures was 0.01% or less, a concentration not found to affect any of the assays performed or the viability of cells as measured by trypan blue dye exclusion or lactate dehydrogenase release.

Opsonized zymosan was prepared by incubating zymosan particles in fresh normal human serum (15 mg/mL) for 30 minutes at 37°C in a rocking water bath followed by washing in phosphate-buffered saline solution and then resuspending in HEPES buffer.

Accepted for publication March 28, 1989.

This study was presented in poster format at the 1987 North American Cystic Fibrosis Conference, Toronto, Canada, October 15, 1987.

Reprint requests to Department of Pediatrics, 22-387 MDCC, UCLA Medical Center, Los Angeles, CA 90024 (Dr Roberts).

Buffer solutions were prepared by using Hanks balanced saline solution, which includes 1.6 mmol of calcium chloride, 0.2 mmol of magnesium sulfate, 0.1 mmol of magnesium chloride, and 11 mmol of glucose, and buffered with 10 mmol of HEPES adjusted to pH 7.35. In some experiments, calcium and magnesium were omitted from the buffer.

Separation of PMNs

Peripheral blood obtained from normal volunteers and patients by venipuncture was anticoagulated with ethylenediamine tetraacetic acid (EDTA; 0.3% final concentration). The PMNs from both the control and the patient were separated simultaneously on discontinuous Percoll gradients.¹⁴ The Percoll gradients were prepared by diluting Percoll with a density of 1.130 (referred to as 100%) with concentrated ($\times 10$) phosphate-buffered saline solution to obtain an osmolality of 310 to 320 mOsm/kg and then further diluting with $\times 1$ phosphate-buffered saline solution to obtain Percoll concentrations of 62.5% and 75%. A 3-mL volume of the 62.5% solution was placed in a 15-mL conical tube (Falcon 2095, Oxnard, Calif), and then 3 mL of the 75% Percoll was layered below the 62.5% layer by means of a narrow catheter placed at the bottom of the tube. Whole blood (4 mL) that had been diluted 50% with $\times 1$ phosphate-buffered saline solution was then layered over the Percoll gradient. The tubes were centrifuged at 1500 rpm (400g) at 22°C for 25 minutes, resulting in the formation of one band of leukocytes above the 62.5% layer (band I) and another between the 62.5% and 75% layers (band II). Band II was composed predominantly of neutrophils (96% to 99%), with the remainder of cells being eosinophils (1% to 4%) or lymphocytes (0% to 1%). The erythrocytes pelleted to the bottom of the tube, and hypotonic lysis was required to remove residual erythrocytes from band II. The cells were washed twice in phosphate-buffered saline solution and stained with Wright's stain to identify different cell types.

Separation of Monocytes

Separation of monocyte populations also employed Percoll gradients. Whole blood from normal volunteers and patients was anticoagulated with EDTA, diluted 50% with phosphate-buffered saline solution, and concentrated ($\times 10$) phosphate-buffered saline solution was added to increase the osmolality by 60 mEq, which preferentially increased lymphocyte density.¹⁵

The blood was incubated at 37°C for 30 minutes to increase the density of the lymphocytes and thus allow for their separation from monocytes. The blood was then layered over isotonic Percoll (48%) in a 15-mL conical tube. The tubes were spun at 1500 rpm for 25

Fig 1.—Luminometer tracings of chemiluminescence response of polymorphonuclear leukocytes (PMNs) from controls and patients with cystic fibrosis (CF) in response to *N*-formyl-methionyl-leucyl-phenylalanine (FMLP) (10^{-6} mol/L). The cells were tested in the presence (left) and absence (right) of extracellular calcium. There was a 10-minute preincubation at 37°C with cytochalasin B (5 mg/L) before adding FMLP. There was no detectable chemiluminescence response before stimulation at this luminol concentration at these luminometer settings (full scale, 10 mV).

minutes at 22°C, and the resulting cell layer above the Percoll was collected and washed twice in phosphate-buffered saline solution. The cells were $90.0\% \pm 1.0\%$ esterase positive, and $85.8\% \pm 3.8\%$ were monocytes by Wright staining. The remainder of the cells were lymphocytes and less than 1.0% neutrophils. The yield of recovered monocytes was greater than 60%.

Chemiluminescence

Assays for chemiluminescence were done on the LKB 1250 luminometer (LKB-Wallac, Turku, Finland) at 37°C with full scale representing 10 mV. Cells (10^6) were suspended in 1 mL of HEPES buffer containing calcium, magnesium (unless otherwise stated), and luminol (10^{-6} mol/L for PMNs and 10^{-6} mol/L for monocytes). Preliminary experiments had shown that this cell concentration (10^6 /mL) gives maximal chemiluminescence response per cell. Cells were incubated for 10 minutes at 37°C before adding any stimuli. The peak (or peaks for biphasic responses) was recorded in millivolts, and the time to reach the peak was also noted.

Statistical Analysis

A Student *t* test (two-tailed, paired) was used to compare the means (\pm SEMs) of different variables.

RESULTS

PMN Chemiluminescence

Typical tracings of the chemiluminescence responses of PMNs in normal controls and in patients with CF to the chemotactic peptide *N*-formyl-methionyl-leucyl-phenylalanine (FMLP) (10^{-6} mol/L), both in the presence and absence of extracellular calcium as recorded by the luminometer, are shown in Fig 1. All of the cells had been preincubated in cytochalasin B (5 mg/L), which greatly enhances the chemiluminescence response to FMLP. The PMNs in normal controls and patients with CF in the presence or absence of calcium display a biphasic response to FMLP with a rapid first peak that is reached in 40 to 60 seconds, followed by a later second peak at 4 to 6 minutes. It is also apparent that there is a greater decrease in the first peak of normal PMNs than in PMNs of patients with CF when calcium is absent.

Figure 2 (left) compares both the first and second mean peak chemiluminescence responses to FMLP for PMNs from controls and patients ($n = 16$ deter-

Fig 2.—Mean peak chemiluminescence responses of polymorphonuclear leukocytes (PMNs) from controls and from patients with cystic fibrosis (CF) to *N*-formyl-methionyl-leucyl-phenylalanine (FMLP) (10^{-6} mol/L) in the presence (left) and absence (right) of extracellular calcium. The cells had been preincubated in cytochalasin B (5 mg/L) for 10 minutes at 37°C addition of *N*-formyl-methionyl-leucyl-phenylalanine. See Fig 1 and text for explanation of how first and second peaks are defined.

Fig 3.—Mean chemiluminescence peak responses of polymorphonuclear leukocytes (PMNs) from controls and patients with cystic fibrosis (CF) to the calcium ionophore A23187 (10^{-5} mol/L) in the presence and absence of extracellular calcium. The cells had been preincubated in cytochalasin B (5 mg/L) for 10 minutes at 37°C before A23187 was added. The luminol concentration was increased to 10^{-5} mol/L ($\times 10$) in cells tested in the absence of calcium due to their decreased chemiluminescence response.

minations with two patients repeated on different days). The cells had been preincubated in cytochalasin B with calcium (1.6 mmol) present. No difference between PMN responses of normal controls and of patients with CF for the first peak was noted (7.77 ± 1.49 mV for controls; 8.45 ± 2.16 mV for patients with CF), but the second peak of levels of PMNs from patients with CF (3.04 ± 0.48 mV) was significantly greater ($P<.005$) than that of the PMNs of normal controls (1.61 ± 0.26 mV). There was no difference between PMN

responses of normal controls and patients with CF in the time required to reach the second peak (5.00 ± 0.29 minutes for normal controls; 5.03 ± 0.27 minutes for patients with CF).

Figure 2 (right) compares the peak chemiluminescence responses of PMNs from normal controls and in patients with CF in the absence of extracellular calcium ($n=21$ with two patients repeated on different days). The first peak, reflecting activation at the membrane binding level,¹⁶ is decreased by the absence of calcium for both the normal and patient PMNs, but the patient response (6.10 ± 1.09 mV) was greater than that of controls (3.83 ± 0.68 mV; $P<.05$). The second chemiluminescence peak in response to FMLP represents intracellular activity and is myeloperoxidase dependent.¹⁷ The absence of calcium did not decrease the magnitude of the second peak and actually increased the difference between the responses of patients with CF and normal controls (3.70 ± 0.43 mV for patients with CF; 1.61 ± 0.21 mV for normal controls; $P<.001$). Similar results to those performed in the absence of calcium are obtained if EDTA (1 mmol) is present (not shown), indicating that little extracellular calcium is available to the cells. Altering the magnesium concentration did not produce any additional differences in chemiluminescence responses of PMNs from normal controls and pa-

tients with CF.

Stimulation of PMNs with the calcium ionophore A23187 produces a single chemiluminescence peak, and results for patients and controls are shown in Fig 3 ($n=16$ with three patients tested on different days). The cells had been preincubated in cytochalasin B (5 μ g/mL), which enhances the response to the ionophore. The peak chemiluminescence responses of PMNs in patients with CF were greater than that of the controls in either the presence (4.21 ± 0.68 mV for patients with CF; 1.85 mV ± 0.38 mV for normal controls; $P<.005$) or absence (1.21 ± 0.42 mV for patients with CF; 0.40 ± 0.18 mV for normal controls; $P<.01$) of calcium. The time required to reach the peak response to A23187 was not different for PMNs from normal controls and from patients with CF (2.53 ± 0.51 minutes for normal controls; 3.18 ± 0.70 minutes for patients with CF).

The chemiluminescence response of normal and patient PMNs to phorbol myristate acetate (20 ng/mL) was also tested. These cells were tested in the presence of calcium although phorbol myristate acetate directly activates protein kinase C and is not strictly dependent on extracellular calcium.¹⁸ The peak response was 10.2 ± 2.2 mV for the normal PMNs and 15.2 ± 1.9 mV for the patient PMNs ($P<.001$; $n=23$ with three patients tested on different days).

The time required to reach the peak response to phorbol myristate acetate was not different for PMNs from normal controls and patients with CF (4.85 ± 0.32 minutes for normal controls; 4.94 ± 0.34 minutes for patients with CF). The results of these chemiluminescence experiments are summarized in Table 1.

Monocyte Chemiluminescence

Monocytes in normal controls and in patients with CF were stimulated with serum-opsonized zymosan in the presence or absence of calcium (Fig 4). The chemiluminescence response of monocytes is similar to that of PMNs to FMLP in that there is a rapid first peak reached within 40 to 60 seconds followed by a second peak or plateau at 4 to 6 minutes. In the absence of calcium (Fig 4), the first peak is barely detectable for normal monocytes. The first peak is also diminished in the patient monocytes in the absence of calcium but is still prominent compared with the tracings of normal monocytes.

Figure 5 shows the peak chemiluminescence responses for both the first and second peaks for the monocytes of normal controls and of patients with CF in the presence (left) and absence (right) of extracellular calcium ($n=9$). The patient monocyte response in the presence

of calcium was greater than that of normal monocytes for both the first peak (3.91 ± 0.97 mV for normal controls; 12.28 ± 2.8 mV for patients with CF; $P<.005$) and the second peak (2.20 ± 0.46 mV for normal controls; 6.20 ± 1.22 mV for patients with CF; $P<.005$). The chemiluminescence responses for monocytes of normal controls and patients with CF were lower in the absence of calcium, but the relative differences for both the first peak (0.29 ± 0.07 mV for normal controls; 1.89 ± 0.42 mV for patients with CF; $P<.005$) and the second peak

(1.33 ± 0.52 mV for normal controls; 4.45 ± 1.09 mV for patients with CF; $P<.01$) were greater.

COMMENT

The PMNs and monocytes from patients with CF released greater amounts of ROI as measured by chemiluminescence after stimulation with a variety of agents. Other investigators have also examined the oxidative potential of phagocytes from patients with CF, as noted in Table 2. Graft et al¹⁹ compared the chemiluminescence response to zymosan of PMNs from nor-

Table 1.—Peak Chemiluminescence Responses of Polymorphonuclear Leukocytes*

Stimuli	Normal Controls, mV	Patients With CF, mV	P
FMLP with calcium†			
First peak	7.77 ± 1.49	8.49 ± 2.16	NS
Second peak	1.61 ± 0.26	3.04 ± 0.48	<.005
FMLP without calcium†			
First peak	3.83 ± 0.68	6.10 ± 1.09	<.05
Second peak	1.61 ± 0.21	3.70 ± 0.43	<.001

§Values are given as range; means were not available.

mal controls with that in adolescents with CF (mean age, 15.3 ± 2.8 years) and found no difference in the height of the peak response. However, the peak response was reached more rapidly in the patients with CF. The authors concluded that PMNs were in a "primed" state in CF and did find a correlation between lower National Institute of Health, Bethesda, Md, clinical scores and a more rapid onset of the peak response. Regelman et al²⁰ compared the monocyte chemiluminescence responses of controls, of carriers of the gene for CF (obligate heterozygotes), and of patients with CF (aged 2 to 40 years). They found no differences in the chemiluminescence response to zymosan or phorbol myristate acetate but did find

that the adherence-stimulated chemiluminescence responses of the carriers and patients were significantly greater than those of controls. Kemp et al²¹ found a decreased chemiluminescence response and lysosomal enzyme release from PMNs of patients with CF when stimulated by FMLP but no difference between PMNs in patients with CF and normal controls when enzyme release was stimulated by calcium ionophore or opsonized zymosan.

Our results differ from these studies in that we found that both PMNs and monocytes from patients with CF were more active than those in controls for most of the stimuli tested. These differences may be due in part to the fact that our patient population was almost 10

years older than patients in the other studies (Table 2). If the propensity for enhanced phagocytic cell activity is an intrinsic property in CF (as suggested by Regelman²⁰), then cells from these patients may become more activated or "primed" by chronic infections as the patient gets older. Bacterial infections have been shown to increase the oxidative activity of PMNs in diseases other than CF.²²⁻²⁴ Patients with CF also develop circulating immune complexes as the disease progresses, and these complexes may also activate PMNs and monocytes.^{25,26}

Kemp et al²¹ found a decreased response of PMNs from patients with CF in contrast to the other three studies (Table 2). The study by Kemp et al also differs from the three other studies in that luminol was not used to enhance the chemiluminescence response. Kemp and colleagues instead used a liquid scintillation counter to measure "native" chemiluminescence, which is primarily dependent on superoxide release from the PMNs.²⁷ Luminol-enhanced chemiluminescence is dependent on myeloperoxidase and the formation of hypohalous acid and other ROIs.²⁸⁻³⁰ Thus, one difference between the Kemp et al study and the others is that different ROIs are being measured as they are released from the cells (Table 2). This may indicate that PMNs and monocytes from patients with CF release relatively more myeloperoxidase-depen-

dent ROIs than they do other ROIs.

The increased release of myeloperoxidase-dependent, halogenated oxidants as measured by luminol-enhanced chemiluminescence has potentially important clinical significance due to the greater toxicity of halogenated ROIs. Hypochlorous acid is the predominant halogenated product of neutrophils, whereas eosinophils preferentially generate hypobromous acid at physiologic concentrations of bromide.³¹ Hypochlorous acid is able to oxidize membrane lipids and proteins, leading to cell death.³² The α_1 -proteinase inhibitor that protects lung tissues from excessive elastase-mediated tissue damage may be inactivated by exposure to hypochlorous acid or long-lived nitrogen-chloride derivatives.³³ Chlorinated ROIs may also activate latent neutrophil collagenase and lead to further tissue damage.³² Hypochlorous acid can also cross-link immune complexes, making the immune complexes long-lived and enhancing their inflammatory properties.³⁴ Alginic acid purified from *P aeruginosa* has the ability to scavenge hypochlorous acid, thus protecting the *Pseudomonas* organism that may have particular relevance to CF.³⁵

All of the CF subjects in the present study were ambulatory outpatients at the time of test results, although most already had some degree of respiratory impairment evidenced by decreased pulmonary function testing, and all were colonized with *P aeruginosa*. No correlation between the phagocytic chemiluminescence responses and the decrease in pulmonary functions has as yet been noted in our study. A negative correlation was found, however, between the erythrocyte sedimentation rates and pulmonary functions of patients with CF (forced vital capacity, $r = -.912$ and $P < .01$; forced expiratory volume in 1 second, $r = -.951$ and $P < .001$), suggesting that the patient's clinical status worsens as the inflammatory processes within the lungs increase. A longer study with a larger number of patients with CF may be necessary to determine what effect factors such as initial colonization with *Pseudomonas*, age, and acute illness have on phagocyte oxidative responses.

The increased release of ROIs from phagocytosis cells is also suspected to

play a damaging role in many other diseases, such as rheumatoid arthritis and inflammatory bowel disease. We have found in an unrelated study that monocytes from patients requiring hyperalimentation for inflammatory bowel disease had a chemiluminescence response to opsonized zymosan that is more than twice the response of normal controls or patients requiring hyperalimentation without inflammatory bowel disease.³⁶ Others^{37,38} have also found increased oxidative responses from both monocytes and alveolar macrophages from patients with inflammatory bowel disease. Thus, although the cause of CF and these diseases differs, the generation of phagocytic cells with increased potential to release ROIs may perpetuate the inflammatory response, whether in the lung or the bowel, and exacerbate the disease process.

Several studies have demonstrated abnormalities in calcium flux or calcium levels in the cells of patients with CF.³⁹⁻⁴² Increased levels of cytosolic calcium have been reported in patient PMNs and mononuclear cells,^{43,44} but Suter et al⁴⁵ did not find differences in cytosolic calcium when patient and normal neutrophil levels were compared. Waller et al⁴⁶ did find that total cell calcium was greater in lymphocytes from patients with CF, although the cytosolic calcium levels were the same as controls. Increased chemiluminescence production of the patient cells in the absence of calcium in our study may indicate an abnormality in calcium metabolism or may reflect that these cells are in a "primed" state and need less calcium for activation. Kemp et al²¹ did find that PMNs in patients with CF were more resistant than PMNs in normal controls to calcium antagonists in regard to inhibition of β -glucuronidase release in response to FMLP stimulation.

Chronic inflammation may increase the calcium content of PMNs, as noted in a study of patients with rheumatoid arthritis whose total calcium content of their PMNs was increased fivefold compared with normal PMNs.⁴⁷ The authors also found that oral prednisone therapy resulted in a decrease in the calcium content of the PMNs in these arthritic patients.

Auerbach et al⁴⁸ found in a 4-year double-blind study that patients with CF

who were receiving alternate-day prednisone had increased growth, better pulmonary functions, and fewer hospitalizations than patients not receiving corticosteroids. Although corticosteroids may influence many factors affecting the clinical status of patients, the improvement of patients with CF who are receiving prednisone may indicate that the increased inflammatory response rather than progressive infection due to impaired immunity is responsible for the pathologic lung condition in CF. The clinical significance of this exaggerated inflammatory response appears to be limited to the lungs in CF, although patients with CF have developed leukocytoclastic vasculitis associated with exacerbations of their pulmonary disease.^{49,50}

Increased phagocytic cell activity could be damaging to the patients with CF by the destruction of protective antibodies in the lungs as previously discussed.^{9,13,51} High serum immunoglobulin levels have paradoxically been associated with an adverse outcome in CF. Patients with hypogammaglobulinemia and CF were found to have a better prognosis than those with normal or increased gamma globulin levels.^{52,53} Patients with higher titers of serum antibodies specific to *P aeruginosa* actually have worse pulmonary function and decreased survival compared with that in patients with lower titers.⁵⁴⁻⁵⁷ Circulating immune complexes that may increase the oxidative responses of PMNs have also been correlated with a worse clinical outcome in CF.^{58,59}

Thus, the propensity for pulmonary infections in CF is not due to a lack of specific immune responsiveness but may be due to the excessive inflammatory responses within the lungs.

This study was supported in part by grants GI517-02 and C008-03 from the Cystic Fibrosis Foundation, Bethesda, Md.

The authors thank Karen D. Dunn, MD, and Joan Kucia for their help in obtaining blood samples from the patients with CF, and Winifred Cole and Leticia Gutierrez for secretarial assistance.

Gastroesophageal Reflux-Induced Hypoxemia in Infants With Apparent Life-Threatening Event(s)

Cynthia C. See, MD; Leonard J. Newman, MD; Stuart Berezin, MD; Mark S. Glassman, MD; Marvin S. Medow, PhD; Allen J. Dozor, MD; Steven M. Schwarz, MD

• To evaluate relationships between gastroesophageal reflux (GER) and the development and onset of apparent life-threatening event(s) (ALTE), 16 infants presenting with ALTE and 6 control subjects manifesting clinical GER alone were studied using prolonged, esophageal pH monitoring in conjunction with simultaneous pulse oximetry and transthoracic impedance pneumocardiography. Despite the absence of a clinical vomiting history in 14 of 16 patients with ALTE, the incidence of GER was similar in both groups (patients with ALTE vs control subjects, 95% vs 100%). Significant arterial oxygen desaturation ($<90\%$ for >3 minutes) was monitored during 60 episodes in 14 of 16 infants with ALTE, compared with no episodes of reduced arterial oxygen saturation in control subjects. Fifty-four of 60 of these desaturation events commenced within 3.9 ± 0.4 minutes (mean \pm SD) of onset of a drop in esophageal pH to less than 4.0. Linear regression analysis indicates a significant correlation between duration of esophageal acidification and length of individual hypoxemic episodes ($r = .39$). Pneumocardiograms were normal in all patients. These data suggest that unsuspected GER is common in infants presenting with ALTE and, in these patients, GER may be directly associated with reflex hypoxemic episodes. Prolonged intraesophageal pH monitoring, performed simultaneously with evaluation for apnea, should be considered in all infants presenting with ALTE.

(AJDC. 1989;143:951-954)

Gastroesophageal reflux (GER) has been implicated in the development and onset of infantile apnea. For example, esophageal pH monitoring, used in conjunction with pneumocardiography and nasal thermistor recording, has documented obstructive apnea occurring during GER episodes.¹⁻⁴ Recently, a newer classification of apneic syndromes of infancy, termed apparent life-threatening event(s) (ALTE), has been proposed.⁵ Previously referred to as "near-miss" sudden infant death syndrome, ALTE defines a symptom complex comprising apnea plus some combination of color change (ie, pallor, cyanosis, altered muscle tone, and choking or gagging).⁵ Episodes can occur while awake during the immediate or late postprandial period,¹ or onset of ALTE can present during sleep.⁶⁻⁸

Clinical follow-up studies suggest that infants with ALTE are at increased risk for development of sudden infant death syndrome. In infants presenting with ALTE, we have reported that a high percentage demonstrate significant GER,⁹ occurring both during sleep and in the immediate postprandial period, when evaluated according to previously established criteria.¹⁰⁻¹² Furthermore, GER is observed in a significant proportion of these patients despite the absence of a clinical history of regurgitation. To date, however, a precise relationship(s) between GER and ALTE has not been addressed. Accordingly, the aim of this study was to determine whether episodes of esophageal acidification in infants with ALTE are associated with abnormalities in cardiorespiratory function.

METHODS Study Groups

Characteristics of the patient population studied are shown in Table 1. From July 1,

1987, to December 31, 1987, 16 infants referred because of an ALTE episode were admitted to the Infant Apnea Center at Westchester County Medical Center, New York Medical College, Valhalla, NY, for evaluation. The patients were evaluated prospectively. Only 2 of 16 of these infants presented with a clinical history of vomiting/regurgitation. A group of contemporary control subjects was comprised of 6 age-matched infants with vomiting, resulting in poor weight gain and/or severe family disruption. None of the control subjects manifested symptoms associated with ALTE. All infants in both groups were products of full-term pregnancies with uneventful perinatal courses, including absence of chronic cough and/or wheezing.

Patient Evaluation

Complete blood cell counts and levels of serum electrolytes, blood urea nitrogen, creatinine, calcium, magnesium, and glucose as well as urinalysis results were within normal limits in all infants at the time of admission. Evaluation of infants with ALTE also included chest roentgenograms, electrocardiograms, echocardiography, 24-hour Holter monitoring, and electroencephalography. To assess relationships between esophageal acidification and cardiorespiratory function, all infants in both study groups underwent simultaneous 16- to 20-hour esophageal pH monitoring, continuous pulse oximetry, and transthoracic impedance pneumocardiography, according to the techniques described below.

Esophageal pH Monitoring.—Gastroesophageal reflux was evaluated using an ambulatory pH monitor (Biosearch Inc, Somerville, NJ), as we have described.¹³ Briefly, a 5F siliconized rubber catheter with a monocrystalline antimony pH electrode embedded at the tip, was passed through the nares and positioned in the distal esophagus according to the method of Strobel et al.¹⁴ To achieve esophageal acidification during oral feedings, unsweetened apple juice (300 mL/m², pH 3.5) was administered twice at 3-hour intervals, before resuming normal formula feeding.

Table 1.—Clinical Presentation of Infants With Apparent Life-Threatening Event(s) (ALTE) and Control Subjects

Category	Patients With ALTE (n=16)	Control Subjects (n=6)
Age range, mo (mean \pm SD)	0.25-10.0 (2.4 \pm 0.6)	0.5-3.0 (2.0 \pm 0.5)*
Vomiting/regurgitation (%)	2/16 (12.5)	6/6 (100)†
Apnea and Pallor/cyanosis (%)	11/16 (68.8)	0/6 (0)†
Muscle-tone changes (%)	2/16 (12.5)	0/6 (0)†
Choking/gagging (%)	3/16 (18.8)	0/6 (0)†

*P = not significant.

†P < .001.

Table 2.—Intraesophageal pH and Oximetry Data Monitored For a Period of 16 to 20 Hours in Control Subjects and Infants With Apparent Life-Threatening Event(s) (ALTE)

	Patients With ALTE	Control Subjects	P
Gastroesophageal reflux episodes per patient, mean No.	28.8	26.5	NS*
Desaturation events (saturated oxygen <90% for >3.0 min) total No.	60	0	<.01
Events associated with esophageal pH <4.0, total No.	54	0	<.01
T-onset of oxygen desaturation following esophageal pH drop to <4.0, min (mean \pm SD)	3.9 \pm 0.4
T-duration of oxygen desaturation, min (mean \pm SD)	7.3 \pm 0.5

*NS indicates not significant.

For the purposes of this study, GER was defined as follows:

1. Immediate postprandial GER is indicated by a pH less than 4.0 during greater than 12 minutes of the initial 2 hours after feeding.¹⁰

2. Awake, delayed postprandial GER is indicated by a pH less than 4.0 persisting greater than 30 seconds in a minimum of 2 separate episodes during the third postprandial hour.¹

3. Sleep GER is indicated by an esophageal pH less than 4.0 during greater than 4 minutes while asleep, beyond the 2-hour postprandial period.¹¹

Pulse Oximetry.—Continuous arterial oxygen saturation (Sao₂) was measured using a Nellcor N-100 pulse oximeter (Nellcor Inc, Hayward, Calif) with the oxygen sensor attached to the right great toe.^{15,16} Sao₂ data were recorded and temporally synchronized with the esophageal pH monitoring device. To exclude technical artifacts inherent in pulse oximetry, only episodes of Sao₂ less than 90% that persisted for greater than 3 minutes were considered significant.

Transthoracic Impedance Pneumocardiography.—Impedance pneumocardiography was performed employing a Healthdyne/Trend event recorder (Healthdyne Inc, Marietta, Ga). Abnormal tracings were defined as follows: (1) apnea (absence of chest wall movement) for greater than 15 seconds and (2) bradycardia and/or periodic breathing exceeding age-related norms.¹⁷⁻¹⁹ During

the study period, detailed infant activities (feeding, ALTE symptoms, and awake and sleep periods) were recorded in individual patient diaries. These observations were correlated with monitoring data as described above. Results were hand scored separately by an investigator unfamiliar with the patient, and diaries and recordings were not identified with patients' names. Audible alarm systems were not employed. All infants were studied after obtaining informed parental consent and this protocol was approved by the Committee for the Protection of Human Subjects (Institutional Review Board), New York Medical College.

Statistical Analysis

χ^2 Analysis and Student's *t* test for unpaired data were used to compare monitoring results between infants with ALTE and control subjects. Data correlating relationships between esophageal acidification and desaturation were analyzed using linear regression and one-way analysis of variance.

RESULTS

Pneumograms did not reveal apnea, bradycardia, or periodic breathing. Data collected from pH and oximetry monitoring in both patients with ALTE and control groups are summarized in Table 2. In infants with ALTE, despite the absence of a clinical vomiting history

Fig 1.—Correlation between length of individual reflux episodes and associated oxygen desaturation events.

in all but 2 patients (Table 1), a total of 491 GER episodes were monitored in 15 of 16 infants (mean number of episodes, 28.8 per patient), compared with 159 episodes documented in 6 of 6 control subjects (mean number of episodes, 26.5 per patient). However, dramatic differences in the incidence of hypoxemic events between groups was noted.

Prolonged, ie, greater than 3 minutes, Sao₂ reductions were observed in none of the control subjects. Conversely, a total of 60 episodes of desaturation were monitored in infants with ALTE (P < .01), and 54 of 60 of these episodes commenced during a period of esophageal desaturation (pH < 4.0). Temporal correlation between esophageal pH and pulse oximetry recordings demonstrates that onset of significant reflux-associated hypoxemia occurred within 3.9 \pm 0.4 minutes (mean \pm SD) following a decrease in esophageal pH to less than 4.0, with a mean duration of 7.3 \pm 0.5 minutes for each desaturation event.

As shown in Fig 1, linear regression analysis of combined pH and oximetry data indicates a significant correlation (P < .05) between the duration of individual periods of esophageal acidification and associated hypoxic episodes. Results of monitoring demonstrate that Sao₂ reductions occurred during feeding, during the immediate postprandial period, and during sleep (Fig 2). There were no episodes of awake, delayed postprandial GER associated with hypoxemia. Similar to our earlier reported data,⁹ while the overall incidence of GER (determined according to the above described criteria) was similar in both patient groups, infants with ALTE had a markedly increased incidence of GER during sleep (Fig 2) when compared with control subjects (77% vs

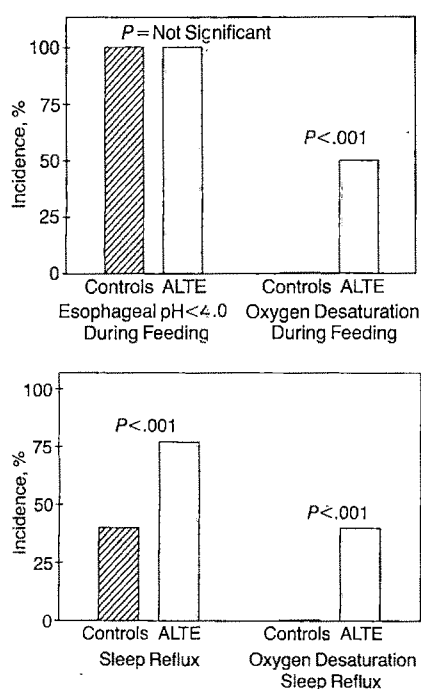

Fig 2.—Top, Incidence of esophageal acidification and oxygen desaturation during feeding. Bottom, Incidence of esophageal acidification and oxygen desaturation during sleep. ALTE indicates apparent life-threatening event(s).

40%, respectively; $P < .001$). Throughout the monitoring period, infants with ALTE manifested an overall 93% incidence of significant hypoxemia associated with reflux (0% in control subjects, $P < .001$), and sleep reflux-related SaO_2 reduction occurred in 40% of patients with ALTE (0% in control subjects, $P < .001$).

To assess the contribution of esophageal acidification per se to the development of hypoxemia, apple juice feedings (pH 3.5, see "Methods" section) were given to both infants with ALTE and control subjects, and a lower esophageal pH of less than 4.0 was achieved in all patients. However, while control sub-

jects demonstrated a 0% incidence of hypoxemia during oral apple juice feedings, 50% of infants with ALTE demonstrated significant acid-induced SaO_2 decreases (Fig 2).

COMMENT

These data demonstrate that clinically inapparent, but significant, oxygen desaturation (in the presence of chest wall movement) occurring during both awake and sleep periods is temporally associated with GER in a group of infants presenting with ALTE. Conversely, in control subjects manifesting vomiting/regurgitation without evidence of cardiorespiratory compromise, GER does not result in significant SaO_2 reduction. Intraesophageal pH monitoring results also confirm our previous observations suggesting that GER occurs in a high percentage of patients with ALTE, despite absence of a clinical history of vomiting.⁹ Finally, linear regression analysis demonstrates a significant correlation between the duration of individual GER episodes and associated hypoxemic events.

Experimental evidence supports an association between GER and alterations in cardiopulmonary function. In newborn piglets, Kenigsberg et al²⁰ observed reflex bradycardia occurring following reduction of esophageal pH to less than 3.5. Using a feline model, Tuchman and colleagues²¹ demonstrated that microaspiration into the trachea is a more likely mechanism for bronchospasm associated with GER than simple acid reflux into the esophagus.

Previous clinical studies indicate a causal relationship between esophageal acidification and the onset of obstructive apnea.^{2,3,22-25} For example, an increased incidence of GER was noted in infants with a history of apnea, and res-

piratory compromise has been reported in infants following regurgitation episodes.^{22,23} Using simultaneous esophageal pH, nasal airflow, and impedance pneumocardiographic monitoring, observations by Herbst et al² and Spitzer and colleagues¹ indicate a direct relationship between GER and the onset of obstructive apnea (ie, reduced nasal air flow in the presence of chest wall movement). In contrast to these data, other investigators have failed to demonstrate a GER/hypoxia association.²⁶ However, failure to assure gastric acidification with the use of apple juice or 5% dextrose in water feedings¹⁹ may account for these monitoring differences.

Although our results indicate an association between the presence of esophageal acid and the incidence of relative oxygen desaturation, none of the infants studied developed symptoms of ALTE during the 16- to 20-hour monitoring period.

Therefore, a conclusive cause-and-effect relationship between GER and the development of apneic syndromes remains to be established. Additional monitoring data, including follow-up studies of these infants during and after long-term medical management for GER, should clarify this issue. Nevertheless, evidence demonstrating that the severity of GER-induced hypoxemia may be related to the duration of esophageal acidification is intriguing and warrants further investigation.

Finally, monitoring data suggesting a direct relationship between the presence of esophageal acid and a reduction in oxygen saturation (SaO_2) in infants with ALTE support the use of prolonged intraesophageal pH studies in patients presenting with an ALTE.

This study was supported in part by a Research Development Award from New England Critical Care Inc, Marlborough, Mass.

The Importance of Parents' Concerns About Their Child's Development

Frances P. Glascoe, PhD; William A. Altemeier, MD; William E. MacLean, PhD

• Parents are often concerned about their child's development, but it is unknown whether concerns indicate actual developmental problems. Pilot studies within 96 families showed that parents' concerns about their children's development took the form of value judgments, could be classified into commonly accepted developmental domains, and related to performance on screening tests. In our study, 100 families seeking pediatric care were asked to list any concerns about their child's development while their children received developmental screening. Eighty percent of the children who failed screening had parents with concerns about articulation, language, fine-motor skills, or global development. Ninety-four percent of the children who passed screening had parents with no concerns or concerns in other developmental areas. The types of concerns parents raised did not vary significantly with level of education, experience in child rearing, or other demographic variables. These results suggest that parental concerns may be a helpful adjunct to standardized developmental screening.

(AJDC. 1989;143:955-958)

Parents seeking care from their child's pediatrician often have concerns about development and other psychosocial issues. In 1983, Hickson et al¹ showed that 70% of parents in pediatric waiting rooms were less worried about medical issues than about discipline, behavior, personality, and social development. Despite this prevalence, the pres-

ence of psychosocial concerns does not often lead to active intervention by pediatricians for two reasons. First, parents often fail to raise psychosocial concerns. Hickson et al¹ found that only 28% of parents indicated that they had discussed or planned to present their most important nonmedical concern to the pediatrician. Second, pediatricians may be reluctant to respond to psychosocial concerns² perhaps because of limitations in reimbursement, time, training, or interest.

The importance of parents' concerns about their child's development is unknown. Does a developmental concern reflect a child's true deviation or does it simply express parental anxiety? In our study, we systematically elicited parental concerns about child development to assess their importance. The purpose was to (1) identify the range of concerns parents have about their child's development, (2) evaluate the relationship between parents' concerns and their child's developmental status, and (3) consider how parents derive their concerns. The results may guide pediatricians in responding to parental concerns about development.

SUBJECTS AND METHODS

The first of two pilot studies helped sample and classify parental concerns. Fifty parents, randomly selected in equal numbers from general pediatric and developmental clinics, were asked, "Please tell me any concerns you have about the way your child is learning and developing." Categories of responses were extrapolated by searching for contrasts and similarities across and within responses.^{3,4} The Table presents representative answers in the 12 categories, 10 of which addressed the commonly accepted developmental domains.

The second pilot study determined whether the concerns of a second group of parents fit into the above 12 categories and whether concerns could be grouped into two types—

those more likely and those less likely to reflect actual developmental problems. Subjects included 46 parent-child dyads drawn equally from the same sites. Parents were asked the same experimental question, and children received developmental screening using a variety of standardized measurements.

No additional categories of concerns were needed. Reliability of categorization was assessed by having two researchers independently code responses on 20% of the cases. There was 80% to 100% agreement, with a mean of 95% agreement for each of the 12 categories. Children who passed screening tended to have parents with either no concerns or concerns about their children's behavior control, social-affective skills, personal-adaptive skills, medical-sensory status, gross-motor skills, or school skills. These responses were labeled group A. Children who failed screening tended to have parents with concerns about their children's articulation, expressive language, receptive language, fine-motor skills, or global development. These responses were labeled group B.

Subjects and Sites

Subjects included 108 parent-child dyads seeking outpatient pediatric care in either a private children's hospital or a city-supported hospital. Subject selection was made according to the availability of families. Parents of children who were not acutely ill or older than 6 years were asked to participate. Eight subjects declined to participate in the study and 100 gave informed consent. The 100 parents were mainly from urban or suburban settings (85%), mothers (85%), married (58%), and had an education level of 12th grade or more (71%). The children were typically white (54%), male (56%), firstborn (54%), siblings (66%), and averaged 37 months of age (range, 2 weeks to 71 months; SD, 20.5 months).

Measurement

Parents were asked the following questions: (1) "What concerns do you have about your child's learning and development?" (2) "How do you know what a child (the same age as your child) should be doing? What kinds of

Categories of Parental Concerns About Children's Development	
Category	Typical Responses
No concerns	Development is normal; typical child; coming along just fine
Behavior control	Stubborn; overly active; short attention span; spoiled; aggravating; throws fits; only does what she wants
Social-affective skills	Wants to be left alone; mood swings; clingy; whiney; bothered by changes; angry; disinterested in usual things; easily led; easily frustrated; immature
Personal-adaptive skills	Won't do things for himself; won't tell me when she is wet; not toilet trained yet; still wants a bottle
Medical-sensory status	Ear infections; asthma; small for age; sick a lot
Gross-motor skills	Clumsy; walks funny; can't ride a bike yet; falls a lot; limps; poor balance
School skills	Can't write his name (scored also with fine motor); doesn't know colors or numbers; just not learning to read; can't remember letter sounds; knows stuff one day but not the next
Articulation	Not making speech sounds correctly; hard to understand; stutters; sounds funny when he talks
Expressive language	Not talking like he should; uses short sentences; can't always say what she means; doesn't always make sense
Receptive language	Doesn't understand what we say to him; doesn't listen well
Fine-motor skills	Can't stay in the lines when he colors; can't write name; can't draw shapes; can't hold a pencil correctly; can't get food to mouth with a spoon yet
Global development	Seems behind; learns slowly; problems with learning; late to learn to do things; slow learner; learns but takes his time

information do you use to figure out how he or she is developing?" (3) "Has anyone ever had concerns about his or her development, such as a physician, teacher, friend, or relative?" (4) "Has his or her development ever been tested?" Parents were also asked to provide demographic and other parent-child data, ie, numbers of children in the family, child's birth order, child's participation in day-care, parents' exposure to handicapped relatives, parents' level of education, area of residence, hours per weekday spent with the child, and perceptions about children's medical problems rated as very serious, somewhat serious, or not very serious.

Children's development was assessed with the screening subtest of the Developmental Profile-II (DP-II),⁵ which was standardized in 1982 on a nationally stratified sample of 3008 children. Subtest items assess the better predictors of subsequent school performance—cognitive, expressive, and receptive language and fine-motor and preacademic or academic skills.^{6,7} Scores correlate highly with individually administered measurements of intelligence, and quotients of 70 or less are considered failing.^{5,8} Parent reporting, direct testing, or both can be used, and measurement decisions were left to the examiner, who had a PhD in child development. Because the DP-II does not screen for articulation impairments, the single most common handicapping condition,⁹ when parents raised concerns about speech, children were also administered the Articulation Screening Test¹⁰ as were an equal number of children whose parents were not concerned about articulation. Children who failed either test were scored as failing. The experimental interview and developmental mea-

surement(s) were administered by the same examiner, with the order of administration alternated to minimize examiner bias and measurement effects.

RESULTS

The Relationship Between Parents' Concerns and Screening Test Results

Seventy-nine of the 100 parents gave group A responses. Fifty-five parents had no concern about development, and 24 had concerns about behavior control (4% of 100), personal-adaptive skills (2%), social-affective skills (4%), gross-motor skills (6%), medical-sensory status (2%), or school skills (4%). Eighty of the 100 children passed developmental screening. Of their 80 parents, 55 had no concerns and 20 had concerns about behavior control, personal-adaptive skills, social-affective skills, gross-motor skills, medical-sensory status, or school skills. Thus, 75 (94%) of the 80 parents whose children passed screening had group A responses.

Twenty-one of the 100 parents gave group B responses, including concerns about articulation (9% of 100), expressive language (8%), receptive language (1%), fine-motor skills (2%), or global development (6%). Twenty of the 100 children failed one or both screening tests, a failure rate that exceeds the 12% prevalence of handicapping conditions⁹ and may be caused by the preponderance of subjects at risk for later de-

velopmental problems from preterm birth or lower socioeconomic background. Thus, 16 (80%) of the 20 parents whose children failed screening had group B responses.

Group A and B responses were significantly correlated with screening test performance ($\phi = .72$, $P < .001$).¹¹ Parents whose children failed screening also had a greater number of concerns (mean = 2.05) than had parents whose children passed screening (mean = .36). A *t* test showed these differences were significant ($t[98] = 9.14$, $P < .001$).

How Parents Derive Their Concerns

Most parents (96 of 100) indicated at least one source of information for figuring out how their child was developing (mean = 3.1; range, 0 to 8). Most parents (59% of 96) compared their child with others (eg, "He's up there with the rest of the kids." Or "She can't do what other kids can do."). In terms of development, 43% of the parents thought their children compared favorably with others, while 11% made unfavorable comparisons, and 5% made both types of comparisons. Favorable comparisons correlated slightly with group A responses ($\phi = .17$, $P < .05$) and nonsignificantly with passing screening tests ($\phi = .13$). Unfavorable comparisons correlated significantly with group B responses ($\phi = .40$, $P < .001$) and with failing scores on developmental screening tests ($\phi = .51$, $P < .001$). Other sources of information included talking with medical professionals (40%), reading child-care literature (40%), and knowledge of development gained from previous observation or experience with children (53%).

Twenty-three of the 100 parents reported some prior exposure to the opinions of others—16 mentioned the concerns of physicians, teachers, friends, or relatives, 1 mentioned that her child had had previous developmental testing, and 6 mentioned both. Of the 23 parents, 13 had group B responses and children who failed screening, 6 had group A responses and children who passed, and 4 had responses that did not relate to the screening test results. Thus, prior developmental testing, the opinions of others, or both correlated significantly with the two types of parental responses ($\phi = .59$, $P < .001$).

and with screening test performance ($\phi = .62, P < .001$).

The Relationship of Demographic and Other Parent-Child Characteristics to Parents' Concerns and Screening Results

There were no demographic differences or other differences in parents who gave group A responses vs group B responses or in children who passed vs those who failed screening tests based on the numbers of children in the family; child's birth order; participation in day-care; parents' exposure to handicapped relatives, level of education, area of residence, hours per weekday spent with the child, perceptions of the seriousness of children's medical problems; and whether the interview or screening tests were conducted first. Children's ages correlated significantly with the screening test performance and type of parental response. Older children were more likely to fail screening ($\phi = .40, P < .001$) and to have parents with group B responses ($\phi = .30, P < .001$). The mean ages of children passing and failing screening were 30 months ($SD = 20.1$ months) and 50 months ($SD = 13.3$ months).

Demographic and other characteristics did not seem to influence whether parental responses corresponded to screening test performance. The 91 parents whose responses related to screening results (ie, group A responses and passing screening or group B responses and failing screening) did not have significantly different demographic or other characteristics from the 9 whose responses did not relate to the results.

COMMENT

The use of information from parents in screening development is not new. Standardized tests such as the Denver Developmental Screening Test-Revised and the Minnesota Child Development Inventory use parental report of skills such as dressing and communicating. Similarly, pediatricians often request a history of selected developmental milestones in developmental screening.^{6,7} In fact, it is difficult to find any type of developmental measurement for young children that does not make some use of parental information. Nevertheless, all available tests use pa-

rental report of specific behaviors, and parents play no role in appraising development; this task is left to professionals.

Little is known about the ability of parents to appraise their child's development. However, most parents cannot identify the typical ages at which children achieve various milestones.¹²⁻¹⁷ Since their knowledge of development is limited, it seems unlikely that parents would have skills in appraisal. Nevertheless, the prevalence of parental concerns about development suggests that they think about the subject¹ and may try to determine on their own whether their child's development is appropriate.

In this study, parents were asked to state any concerns about the way their child was learning and developing, and they responded with a range of concerns that could be categorized into commonly recognized developmental domains. Concerns were given in response to an open-ended question rather than to queries about specific skills or behaviors. Parents' answers, although often short and simple, took the form of value judgments. It was unclear to what degree such appraisals were the result of a prior, continuous parental assessment as opposed to opinions first formed in response to the interview, but the frequent mention of comparisons by parents as a method for deriving concerns suggests that the former is more likely.

Concerns about development were common and were expressed by 45% of all parents. While this figure seems high, the range of concerns was broad, with some appearing much less likely to reflect true developmental problems than others. This assumption was supported by a pilot study that indicated that certain groups of concerns were related to failing screening tests while others were not. The absence of concerns or concerns about behavior control, personal-adaptive skills, social-affective skills, gross-motor skills, medical-sensory status, or school skills—identified as group A responses—corresponded with passing screening tests. Concerns about articulation, expressive language, receptive language, or global development—identified as group B responses—were associated with failing screening tests. Although the separation of A and B con-

cerns was made on an experimental basis, it does not deviate substantially from current concepts about the relative importance of developmental domains with the exception of school skills.^{7,18} For example, gross-motor skills concerns were more appropriate for inclusion in group A responses since they are only a weak predictor of overall developmental status.^{6,7} As further evidence that the grouping of concerns was legitimate, parents with group B concerns tended to indicate by comparisons that their children were having actual developmental difficulties, while parents with group A concerns did not. The lack of significance in the demographic or child-rearing variables suggests that parents of differing backgrounds are equally able to assess their child's development, a finding supported by previous research.^{19,20}

How is it that parents' concerns seemed closely related to the developmental status of children, especially when most studies find parents ill-informed about child development?¹²⁻¹⁷ As expected, they did not rely primarily on formal knowledge of development in appraising their children. Instead, the most common method for analyzing development was comparing one's own children with the children of others. The conclusions parents reached through comparisons were highly correlated with types of concerns (A and B responses) and with screening test performance. This suggests that comparisons were an important part of determining concerns about development and their accuracy. Some of the agreement between screening tests and parents' concerns may also be explained by parental exposure to the opinions of others or to previous developmental testing. However, only 23% of parents reported exposure, and parents may have introduced concerns to professionals.

Our study shows a strong relationship between certain types of parental concerns and child development, and although pediatricians should listen to these concerns, we do not recommend relying in any way on concerns as an alternative to standardized developmental screening measures. Nor should pediatricians ignore concerns that currently seem unrelated to screening test performance. Rather, parental con-

cerns about development should be viewed as a helpful adjunct to routine developmental screening and a means for focusing the content of parent-physician communication. Additional research is needed to confirm and extend these findings, including cross-validation with a larger and more stratified population that includes subjects from private pediatric clinics; improvement in research design such that separate examiners "blinded" to each other's data assess parental concerns and development; use of diagnostic developmental tests rather than screening measurements to determine developmental

status; formal, multitrait-multimethod assessment of all developmental areas to determine the exact relationship between the content of parents' concerns and performance in each developmental domain; and a determination of variables influencing the relationship between concerns and screening results (eg, "vulnerable child" syndrome might lead to unwarranted concern, while the perception that a handicapped child is receiving optimal intervention might reduce concerns about delayed development).

Lichtenstein and Ireton,²¹ leaders in developmental screening, suggest that

one of the challenges in working with parents is "how to obtain the precious information they possess in a manner that is not only valid and cost-effective but also instrumental in the process of building positive, working relationships." This article suggests that when parents are concerned about their child's development, health care professionals should pay attention. If our findings are confirmed and extended, the practice of routinely eliciting parental concerns about development might be supported as a simple, brief approach to prescreening child development.

NEW

For the symptoms of allergic rhinitis...

DESIGNED TO DELIVER

Now NASALCROM[®] is available in the ready-to-use pump spray your patients have been asking for! The new NASALMATIC[®] fully-assembled unit comes in two convenient sizes: For your chronic allergic rhinitis patients, the *new* 26 mL size is a handy, economical alternative to the purchase of frequent refills. For your patients with seasonal symptoms, the regular 13 mL size is ideal.

Inside the new NASALCROM unit is the proven formula patients rely on for relief of sneezing, itching, runny nose, and congestion.^{1,2} NASALCROM provides protection from the first dose¹ and symptom relief within days.² And it works without the annoying side effects typical of other first-line allergic rhinitis medications.^{3,4}

Nonsedating NASAL SOLUTION, 40 mg/mL
NASALCROM[®]
(cromolyn sodium/FISONS)

**IN THE NEW FULLY-ASSEMBLED UNITS
(26 mL AND 13 mL)**

Please see adjacent page for Brief Summary of Full Prescribing Information.

NASAL SOLUTION, 40 mg/mL

NASALCROM[®]

(cromolyn sodium nasal solution, USP)

Brief Summary

DESCRIPTION: Each milliliter of NASALCROM[®] Nasal Solution (cromolyn sodium nasal solution, USP) contains 40 mg cromolyn sodium in purified water with 0.01% benzalkonium chloride to preserve and 0.01% EDTA (edetate disodium) to stabilize the solution.

INDICATIONS: NASALCROM is indicated for the prevention and treatment of the symptoms of allergic rhinitis.

CONTRAINDICATIONS: NASALCROM is contraindicated in those patients who have shown hypersensitivity to any of the ingredients.

PRECAUTIONS: General: Some patients may experience transient nasal stinging and/or sneezing immediately following instillation of NASALCROM. Except in rare occurrences, these experiences have not caused discontinuation of therapy. In view of the biliary and renal routes of excretion for cromolyn sodium, consideration should be given to decreasing the dosage or discontinuing the administration of the drug in patients with impaired renal or hepatic function.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Long term studies in mice (12 months intraperitoneal treatment followed by 6 months observation), hamsters (12 months intraperitoneal treatment followed by 12 months observation), and rats (18 months subcutaneous treatment) showed no neoplastic effect of cromolyn sodium.

No evidence of chromosomal damage or cytotoxicity was obtained in various mutagenesis studies.

No evidence of impaired fertility was shown in laboratory animal reproduction studies.

Pregnancy: Pregnancy Category B. Reproduction studies with cromolyn sodium administered parenterally to pregnant mice, rats, and rabbits in doses up to 338 times the human clinical doses produced no evidence of fetal malformations. Adverse fetal effects (increased resorptions and decreased fetal weight) were noted only at the very high parenteral doses that produced maternal toxicity. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Drug Interaction During Pregnancy: Cromolyn sodium and isoproterenol were studied following subcutaneous injections in pregnant mice. Cromolyn sodium alone in doses of 60 to 540 mg/kg (38 to 338 times the human dose) did not cause significant increases in resorptions or major malformations. Isoproterenol alone at a dose of 2.7 mg/kg (90 times the human dose) increased both resorptions and malformations. The addition of cromolyn sodium (338 times the human dose) to isoproterenol (90 times the human dose) appears to have increased the incidence of both resorptions and malformations.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when NASALCROM is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established.

ADVERSE REACTIONS: The most frequent adverse reactions occurring in the 430 patients included in the clinical trials with NASALCROM were sneezing (1 in 10 patients), nasal stinging (1 in 20), nasal burning (1 in 25), and nasal irritation (1 in 40). Headaches and bad taste were reported in about 1 in 50 patients. Epistaxis, postnasal drip, and rash were reported in less than one percent of the patients. One patient in the clinical trials developed anaphylaxis.

Adverse reactions which have occurred in the use of other cromolyn sodium formulations for inhalation include angioedema, joint pain and swelling, urticaria, cough, and wheezing. Other reactions reported rarely are serum sickness, periarteritic vasculitis, polymyositis, pericarditis, photodermatitis, exfoliative dermatitis, peripheral neuritis, and nephrosis.

CAUTION: Federal law prohibits dispensing without prescription.

Radiological Case of the Month

Kenneth R. Katz, MD, Robert W. Emmens, MD (*Contributors*);
Beverly P. Wood, MD (*Contributor and Section Editor*)

A 4-year-old black boy was referred to the emergency department for evaluation of acute dehydration. He had been in good health until 6 months earlier, when he began to eat smaller portions of food and was noted to spit food out and hide it in the furniture. He tolerated liquids well, but often became teary-eyed while attempting to eat. There was a recent history of progressive drooling and nasal congestion. On admission he was afebrile and had diminished skin turgor. His weight was below the third percentile, although he had been in the 40th percentile 9 months earlier. A urinalysis showed specific gravity of 1.032 and trace ketones. The serum electrolyte level was in the normal range. His hematocrit was 0.36, and the white blood cell count was $11.4 \times 10^9/L$, with a differential cell count of 0.29 segmented neutrophils, 0.03 band cells, and 0.53 lymphocytes. The results of a tine test were negative.

An esophagogram was obtained.

Accepted for publication December 20, 1988.

Figure 1.

Esophageal Obstruction and Abscess Formation Secondary to Impacted, Eroding Tiddlywink

Fig 1.—The esophagogram shows an obstruction to passage of barium past the upper thoracic esophagus. Note an extrinsic mass impression narrowing the adjacent trachea (arrow) and an ovoid lucency within the mass.

Fig 2.—The computed tomographic scan shows tracheal displacement (curved arrow) and swallowed contrast filling the mediastinal mass (straight arrow). Note the disc lucency in the mass immediately anterior to the vertebra.

Fig 3.—Sagittal midline magnetic resonance image shows dilated esophagus (solid arrow) and high-signal mass containing disklike low-signal foreign body (open arrow).

The operative exploration of the esophagus revealed a 2-cm-diameter blue, plastic tiddlywink (disk). The object had eroded the upper esophagus and was embedded in granulation tissue adjacent to the lumen. The lumen was obscured by the mass and friable, edematous mucosa. Two weeks following surgery, the patient was discharged, has done well, and has regained his lost weight.

Swallowed foreign bodies are common in children between the ages of 1 and 4 years. The objects most commonly seen in the United States are parts of toys and disks (eg, coins or buttons). Impaction of swallowed objects is rare in children.¹ However, the site of impaction is at the cricopharyngeus in the cervical esophagus or in the upper thoracic esophagus.^{1,2} Although adults with impacted foreign

bodies frequently demonstrate underlying disease, children with impaction are usually normal.²

The impacted foreign body may erode the esophagus by pressure or perforate it if it is sharp. Symptoms from impacted foreign bodies can be subtle. Those noted include wheezing, refusal to eat, increased salivation, pain on swallowing, vomiting, and altered consciousness.³⁻⁶

Examination, including a chest roentgenogram and a contrast esophagogram, usually indicates the diagnosis, especially in the case of a radiopaque foreign body. In our case, the plastic object was mistaken for air within an abscess or mass obstructing the esophagus. Further examination with computed tomography (Fig 2) and magnetic resonance imaging (Fig 3) followed. Plastic demonstrates the

same characteristics as gas on radiography, computed tomography, and magnetic resonance imaging.

We should suspect that a young child with symptoms of esophageal obstruction may have an impacted foreign body, even when it is not easily visible radiographically.

Denouement and Discussion

Fig 1.—Full facial view of hamartoma.

Fig 2.—Left lateral view of hamartoma.

Fig 3.—Close-up of the midface showing hamartoma.

Fig 4.—Striated muscle bundles (hematoxylin-eosin, original magnification $\times 400$).

Congenital rhabdomyomatous mesenchymal hamartoma of the skin, to our knowledge, has been described once previously as a single pedunculated appendage on the chin of a newborn. In that case, the appendage had an abnormal arrangement of dermal mesenchymal elements, with a prominence of skeletal muscle. In the patient shown herein, the connective-tissue core of the pulp contained adipose cells and striated muscle bundles that were oriented primarily parallel to the long axis. The epidermis was slightly hyperplastic and under higher magnification demonstrated striated

muscle bundles. Pathologically, it was characterized as a hamartoma because of the abnormal mixture of normal cells (ie, striated muscle, mesenchyme, and skin) in an appropriate area, the face muscles of expression.

Other than a very unusual appearance, the striking feature was the random contractile movements of the appendages, giving a snakelike appearance. Computed tomographic scan revealed no involvement of underlying bone. A bilateral leukokoria due to sclerocornea was also present, with no retinal detachment detected by computed tomographic scan. Pri-

mary surgical revision resulted in dramatic improvement of the patient's appearance.

This condition, at present, is not known to be associated with anomalies of other organ systems, nor has any inheritance pattern been established. The lesions are not similar to fetal rhabdomyomas or connective-tissue nevi.

Fast Action, Fast Relief in Asthma

Alupent[®]

(metaproterenol sulfate)
Inhalation Aerosol

15 ml; 15 mg/ml (each metered dose delivers 0.65 mg metaproterenol sulfate)

*In controlled single-dose studies with Alupent Inhalation Aerosol, the duration of effect of two to three inhalations (20% or greater increase in FEV₁) has varied from one to five hours. In multiple-dose studies (up to q.i.d.), the duration of effect for a similar dose of Alupent has ranged from about one to two and a half hours.

Please see following page for brief summary of prescribing information

Fast Action, Fast Relief in Asthma

Alupent®

(metaproterenol sulfate)

Tablets	Inhalation Aerosol	Syrup	Inhalation Solution	Inhalation Solution
10 and 20 mg	15 ml†	10 mg/5 ml	5% 10 ml and 30 ml	Unit-dose Vials 0.4% and 0.6%

†15 mg/ml (each metered dose delivers 0.65 mg metaproterenol sulfate)

Brief Summary of Prescribing Information

CONTRAINDICATIONS Use in patients with cardiac arrhythmias associated with tachycardia is contraindicated.

Although rare, immediate hypersensitivity reactions can occur. Therefore Alupent® (metaproterenol sulfate USP) is contraindicated in patients with a history of hypersensitivity to any of its components.

WARNINGS Excessive use of adrenergic aerosols is potentially dangerous. Fatalities have been reported following excessive use of Alupent® (metaproterenol sulfate USP) as with other sympathomimetic inhalation preparations, and the exact cause is unknown. Cardiac arrest was noted in several cases. Paradoxical bronchoconstriction with repeated excessive administration has been reported with sympathomimetic agents. Therefore, it is possible that this phenomenon could occur with Alupent. Patients should be advised to contact their physician in the event that they do not respond to their usual dose of a sympathomimetic amine aerosol.

PRECAUTIONS Because Alupent® (metaproterenol sulfate USP) is a sympathomimetic drug, it should be used with great caution in patients with hypertension, coronary artery disease, congestive heart failure, hyperthyroidism or diabetes, or when there is sensitivity to sympathomimetic amines.

Information for Patients Extreme care must be exercised with respect to the administration of additional sympathomimetic agents. A sufficient interval of time should elapse prior to administration of another sympathomimetic agent.

Carcinogenesis Long-term studies in mice and rats to evaluate the oral carcinogenic potential of metaproterenol sulfate have not been completed. Studies of metaproterenol sulfate have not been conducted to determine mutagenic potential or effect on fertility.

Pregnancy *Teratogenic Effects: Pregnancy Category C.* Alupent has been shown to be teratogenic and embryocidal in rabbits when given orally in doses 620 times the human inhalation dose and 62 times the human oral dose. There are no adequate and well-controlled studies in pregnant women. Alupent should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. Oral reproduction studies in mice, rats and rabbits showed no teratogenic or embryocidal effects at 50 mg/kg, corresponding to 310 times the human inhalation dose and 31 times the human oral dose. Teratogenic effects in the rabbit included skeletal abnormalities and hydrocephalus with bone separation.

Nursing Mothers It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Alupent is administered to a nursing woman.

Pediatric Use Consult package insert for age limit.

ADVERSE REACTIONS Adverse reactions are similar to those noted with other sympathomimetic agents. Adverse reactions such as tachycardia, hypertension, palpitations, nervousness, tremor, nausea and vomiting have been reported.

The most frequent adverse reactions to Alupent® (metaproterenol sulfate USP) Inhalation Solution are nervousness and tachycardia which occur in about 1 in 7 patients, tremor which occurs in about 1 in 20 patients and nausea which occurs in about 1 in 50 patients. Less frequent adverse reactions are hypertension, palpitations, vomiting and bad taste which occur in approximately 1 in 300 patients.

HOW SUPPLIED *Inhalation Aerosol:* Each canister of Alupent® (metaproterenol sulfate USP) Inhalation Aerosol contains 225 mg of metaproterenol sulfate as a micronized powder in inert propellants. Alupent Inhalation Aerosol with mouthpiece (15 ml). Alupent Inhalation Aerosol refill (15 ml). Store below 77°F (25°C). Avoid excessive humidity.

Inhalation Solution: Alupent Inhalation Solution is supplied as a 5% solution in bottles of 10 ml or 30 ml with accompanying calibrated dropper.

Store below 77°F (25°C). Protect from light. Do not use the solution if it is brown or has a precipitate. Alupent Inhalation Solution Unit-dose Vial is supplied as a 0.4% or 0.6% clear colorless or nearly colorless solution containing 2.5 ml with 25 vials per box. Store below 77°F (25°C). Protect from light. Do not use the solution if it is brown or has a precipitate.

Syrup: Alupent is available as a cherry-flavored syrup, 10 mg per teaspoonful (5 ml), in 16 fl. oz. bottles. Store below 86°F (30°C). Protect from light.

Tablets: Alupent is supplied in two dosage strengths as scored, round white tablets in bottles of 100. Tablets of 10 mg coded BI/74. Tablets of 20 mg coded BI/72.

Storage for bottles. Store below 86°F (30°C). Protect from light.

Storage for blister samples. Store below 77°F (25°C). Protect from light.

Consult package insert before prescribing.

Effect of Pancreatic Enzyme Supplements on Iron Absorption

William T. Zempsky, MD; Beryl J. Rosenstein, MD; John A. Carroll, MD; Frank A. Oski, MD

• Iron deficiency has been reported in one third of patients with cystic fibrosis. There are data that suggest that iron absorption is increased with exocrine pancreatic deficiency and that administration of pancreatic enzymes may impair oral iron absorption. We compared oral iron absorption over a 3-hour period in the presence and absence of exogenous pancreatic enzymes in 13 stable young-adult patients with cystic fibrosis and 9 age-matched control patients. Although none of the patients with cystic fibrosis had a hemoglobin level less than 119 g/L, serum ferritin levels were less than 25 µg/L in 5 of the 13 patients, and the mean corpuscular volume was significantly lower in the patient group (86.1 ± 2.7 vs 90.9 ± 5 fL). Baseline mean serum iron levels were higher in controls (18.9 ± 5.9 µmol/L) than in patients (11.9 ± 6.3 µmol/L). There was no difference in iron absorption in the absence of exogenous pancreatic enzymes. Significant impairment of iron absorption was detected in both patients with cystic fibrosis and controls after administration of a preparation of pancreatic enzymes. There was an inverse relationship between iron stores, as measured by serum ferritin, and iron absorption. These findings suggest that long-term consumption of pancreatic enzymes by patients with cystic fibrosis may contribute to iron deficiency.

(AJDC. 1989;143:969-972)

Iron deficiency has been reported in 33% to 66% of patients with cystic fibrosis (CF).¹⁻³ The etiology is probably multifactorial, including inadequate dietary intake, blood loss, iron malabsorption, and chronic infection. There have been both in vitro and in vivo studies that suggest that iron absorption is in-

creased with exocrine pancreatic deficiency^{4,5} and that the administration of pancreatic enzymes may impair oral iron absorption.⁶⁻⁸ Other investigators, however, have not confirmed an effect of pancreatic enzymes on iron absorption.⁹ The purpose of the present study was to investigate iron absorption in young-adult patients with CF and age-matched control patients as well as to measure the effect of a preparation of pancreatic enzymes on iron absorption.

PATIENTS AND METHODS

Patients

Thirteen patients with CF under medical care at The Johns Hopkins Hospital CF Center, Baltimore, Md, and 9 age-matched control patients participated in the study. The control patients were recruited from the medical and nursing staff at the hospital. The study was approved by the Joint Committee on Clinical Investigation of The Johns Hopkins Medical Institutions, and informed written consent was obtained from all subjects. The diagnosis of CF was based on a characteristic clinical picture and two positive quantitative pilocarpine iontophoresis sweat test results. Patients were invited to participate irrespective of their hematologic status. The patients had not experienced a pulmonary exacerbation in the preceding month. None of the subjects had evidence of cor pulmonale, diabetes mellitus, or hepatobiliary or renal disease, nor were they receiving oxygen or drugs known to affect gastric emptying. Among the patients with CF, 11 were taking pancreatic enzyme supplements regularly and 1 was receiving a therapeutic dosage of iron.

Methods

Serum ferritin levels were measured by an immunoradiometric assay (Biorad, Hercules, Calif) and expressed in micrograms per liter (normal, >12.5 µg/L). Serum erythropoietin levels were determined by a radioimmunoassay (Smith Kline & French Laboratories, Philadelphia, Pa) and expressed in units per liter (normal, 4 to 26 U/L). Serum iron levels were measured by a ferrozine assay¹⁰ and expressed in micromoles per liter (nor-

mal, 11.6 to 31.3 µmol/L). Oxygen saturation was determined by pulse oximetry (Nellcor Inc, Hayward, Calif) with the subjects awake and resting. Hemoglobin levels, hematocrit values, red blood cell distribution widths, and mean corpuscular volumes were determined by standard methods.

Studies to determine the absorption of iron given orally were performed by a modification of the method of Crawley.¹¹ After a 12-hour overnight fast during which no medications were given, an intravenous heparin lock was placed, and an early morning venous blood sample was collected for baseline hematologic values. On the first day of the study, elemental iron (2 mg/kg) was administered in the form of liquid ferrous sulfate (25 mg of iron per milliliter), and serum iron levels were measured 1, 2, and 3 hours after iron administration. Within 1 week the protocol was repeated, but in the second study the subjects were given four capsules of a pH-sensitive, enteric-coated, microsphere preparation of pancrelipase (Pancrease, McNeil Pharmaceutical, Spring House, Pa) 1 hour prior to the administration of iron. The mean interval between studies was 3.6 days for the patients and 3.1 days for the controls. No subjects were studied on consecutive days. Absolute increases in serum iron levels as well as percentage increases above baseline were calculated 1, 2, and 3 hours after iron administration. Differences in iron absorption between patients with CF and controls and between subjects with low and normal serum ferritin levels were evaluated by independent group *t* tests. The effect of supplemental pancrelipase was evaluated using paired-differences *t* tests. The *t* tests were calculated using separate estimates of variances in instances where the group variances could not be assumed to be equal.

RESULTS

Characteristics of the patients with CF and control patients on entrance into the study are shown in Table 1. They were closely matched in age. One of the patients with CF had an oxygen saturation of 93%; all others had saturations of 95% or above. The patients with CF weighed significantly less than the controls. Baseline hematologic data for the

*Values are mean ± SD.

†*P* < .001.‡*P* < .05.

patients and controls are shown in Table 2. There was no significant difference in hemoglobin values; the lowest value in either group was 119 g/L. Mean values for red blood cell distribution width, serum ferritin, and serum erythropoietin were similar in patients and controls. However, in 5 patients and 4 controls, serum ferritin levels were less than 25 μg/L. In the patient group, erythropoietin levels ranged from 6 to 20 U/L (mean, 14.5 U/L); there were no elevations. The mean corpuscular volume was significantly lower in patients (86.1 ± 2.7 fL) than in controls (90.9 ± 5.0 fL) (*P* < .001). The mean serum iron concentration was significantly higher in controls (18.9 ± 5.9 μmol/L) than in patients (11.9 ± 6.3 μmol/L) (*P* < .05); 5 of the 13 patients but none of the 9 controls had a serum iron concen-

tration lower than 9 μmol/L. There was no significant difference in baseline mean serum iron levels between study days 1 and 2 in either the patient or control groups.

In the absence of administration of pancreatic enzyme supplements, there was no significant difference in iron absorption between patients and controls (Fig 1). The peak iron level above baseline increased by 311% in the patients and by 230% in the controls (not significant). However, there was significant impairment of iron absorption in both patients and controls after the administration of pancrelipase. In the patient group, 1 hour after iron administration, there was a 62% increase in the serum iron level above baseline in the presence of pancrelipase and a 188% increase above baseline in the absence of pancre-

Fig 1.—Percentage increases in serum iron levels in patients (squares, *n* = 13) and controls (circles, *n* = 9) following the oral administration of elemental iron (2 mg/kg) in the absence of pancreatic enzyme supplements (not significant).

lipase (*P* < .05) (Fig 2). In the control group (Fig 3) and in the patient and control groups combined, percentage increases in serum iron levels as well as peak serum iron levels were significantly higher in the absence of pancrelipase 1, 2, and 3 hours after iron administration. When iron absorption in the absence of pancrelipase was compared in the 9 subjects (5 patients, 4 controls) with serum ferritin levels less than 25 μg/L and in the 13 subjects (8 patients, 5 controls) with serum ferritin values greater than 25 μg/L, peak serum iron levels were significantly higher 1, 2, and 3 hours after iron administration (*P* < .02), and the percentage increase in iron levels was significantly higher 2 and 3 hours after iron administration (*P* < .05) in the group with low serum ferritin levels. Among all subjects there was an inverse relationship between baseline serum ferritin levels and iron absorption (Fig 4).

COMMENT

Our results are consistent with previous findings that iron deficiency is common in patients with CF.¹⁻³ We found a significant reduction in iron absorption, both in patients with CF and in controls, when iron was administered along with pancreatic enzymes. This is consistent with previous studies in which administration of pancreatic enzymes has been associated with reduced oral iron absorption in both healthy controls and

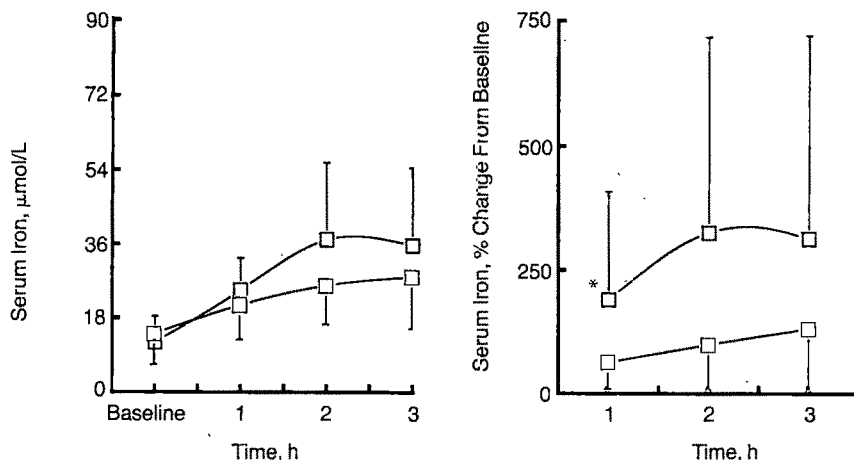

Fig 2.—Comparison of absolute increases in serum iron levels (left) and percentage increases above baseline (right) in the absence (open squares) and presence (solid squares) of pancreatic enzyme supplements in 13 patients with cystic fibrosis. Asterisk indicates $P < .05$.

Fig 3.—Comparison of absolute increases in serum iron levels (left) and percentage increases above baseline (right) in the absence (open circles) and presence (solid circles) of pancreatic enzyme supplements in nine controls. Asterisk indicates $P < .05$.

Fig 4.—Relationship between baseline serum ferritin and peak serum iron concentrations measured over a 3-hour period following the oral administration of elemental iron (2 mg/kg) in patients (solid circles, $n = 13$) and controls (open circles, $n = 9$) in the absence of pancreatic enzyme supplements ($r = -.5$, $P < .02$). The solid line represents the linear regression for patients and controls combined.

zymes on pH has also been postulated. In *in vitro* studies it has been shown that the pH of ferrous sulfate alone is lower than that of a ferrous sulfate-pancreatic enzyme mixture.⁷ The more acid pH of ferrous sulfate alone would favor iron solubility and absorption. However, in an isolated rat jejunum model, iron uptake was inhibited by pancreatic enzymes even when the pH was kept constant.⁸ Alternatively, components of pancreatic enzyme preparations may combine with iron and impair its absorption or may directly injure or bind mucosal iron-binding receptors.

The clinical significance of our observations is difficult to interpret. There are two kinds of iron in the diet with respect to the mechanism of absorption: heme iron and nonheme iron. Heme iron is derived from hemoglobin and myoglobin, and nonheme iron is derived mainly from cereals, vegetables, and fruits.¹⁴ Heme iron is much better absorbed than nonheme iron. The iron employed in this study was nonheme iron, but the bioavailability of ferrous sulfate when given with water, as in our study, is usually much greater than when iron in any form is ingested in a meal. The fact that iron deficiency anemia develops in so many patients with CF who are given pancreatic extract supplement suggests that our observations do have biologic relevance. It should be noted, however, that all of our study subjects were

patients with CF.⁴⁷ It has also been observed that patients with CF who had been receiving pancreatic supplements longer than 1 year had lower hemoglobin and plasma iron levels, as well as impaired iron absorption, compared with untreated patients and controls.⁶ Conversely, increased iron uptake has been observed in patients with pancreatitis and pancreatic insufficiency.⁶ Heinrich et al,⁹ in studies on just three patients, found no difference in iron absorption between patients with CF and controls and no effect of enzymes on iron absorption. In animal studies, ligation of the pancreatic duct has led to an in-

crease in iron absorption,¹² and *in vitro* studies using an isolated rat jejunum preparation have demonstrated inhibition of iron uptake following the administration of pancreatic extract.⁸

The mechanism by which pancreatic enzymes impair iron absorption is not clear. Intraluminal pH may be an important factor, since inorganic iron must first be reduced to the ferrous state to be absorbed. Increased absorption of iron would be expected in patients with pancreatic insufficiency because of a lower intraluminal pH, which favors solubility and reduction of iron to the ferrous form.¹³ An effect of pancreatic en-

adults; the results may not be applicable to growing children.

In patients with CF, an inverse relationship between PaO_2 levels and hemoglobin and hematocrit values has been observed,⁷ but compensatory polycythemia is unusual. A defect in red blood cell production appears to be the primary factor, most likely secondary to a disturbance in erythropoietin regulation and iron availability. Erythropoietin levels were normal in our patients. This is consistent with a previous study in patients with CF in which there was no compensatory increase in erythropoietin relative to the degree of underlying anemia and hypoxemia.² This blunted erythropoietin response is similar to that seen in a variety of inflammatory conditions.^{15,16} Its mechanism in patients with CF is not known.

In conclusion, the iron status of patients with CF should be routinely monitored; the serum ferritin level is proba-

bly the most useful measurement of total body iron stores. Based on our results, we recommend that if supplemental iron is given, it should not be administered in close proximity to administration of pancreatic enzyme supplements.

This study was supported in part by a grant from the Cystic Fibrosis Foundation, Rockville, Md.

Sandra Zubrowski assisted in the preparation of the manuscript.

Risk of Infectious Complications in Well-Appearing Children With Transient Neutropenia

Anthony J. Alario, MD, John S. O'Shea, MD

• To determine whether well-appearing children found incidentally to be neutropenic are at risk for an infectious complication, 44 consecutive months of hematology laboratory records were reviewed. One hundred nineteen patients had medical record documentation regarding clinical course, serial white blood cell counts, and the absence of serious infections, chronic illnesses, or a family history known to be associated with neutropenia. The median duration of documented neutropenia was 13 days (range, 1 to 491 days). Infectious complications occurred in 4 of the 36 patients who had neutropenia for more than 30 days (2 with stomatitis, 1 with cellulitis, and 1 with pneumonia) but in none with shorter durations of neutropenia. There were no significant associations between the development of an infectious complication and either the initial absolute neutrophil count or the lowest documented absolute neutrophil count, nor was there a correlation between the initial absolute neutrophil count and the duration of neutropenia. These data indicate that infectious complications occur in otherwise well children with unexplained neutropenia that persists, but these infections are infrequent and usually are superficial.

(AJDC. 1989;143:973-976)

It is well recognized that children and adults with a chronically suppressed immune system are at an appreciable risk for developing septicemia or a serious focal infection while they remain immunocompromised.^{1,2} In addition, individuals with chronic or immune-mediated neutropenia are also susceptible to mucocutaneous and pyogenic infec-

tions.³⁻⁶ This susceptibility may be particularly evident in childhood, when the other modalities of host defense are not mature.³ The risk of infection in these situations is correlated with both the duration and the degree of neutropenia.^{3,7-9}

Even though isolated neutropenia is common in children who were previously well,¹⁰ pediatricians often become concerned that these children may be at the same significant risk for infection as those who are immunocompromised.^{10,11} The purpose of this study was to determine whether well-appearing children without identified comorbid illness who are found to be neutropenic during minor acute illnesses, routine preoperative screening, or treatment for common childhood conditions are at risk for an infectious complication while they are neutropenic. An additional study purpose was to define the relationships between the duration of neutropenia, the initial and lowest documented absolute neutrophil counts, and the development of infectious complications in this cohort of children.

PATIENTS AND METHODS

Patient Sample and Clinical Data Gathering

Forty-four consecutive months of hospital hematology records for all patients 18 years or younger were reviewed to identify retrospectively children with neutropenia, defined as an absolute neutrophil count of $1.5 \times 10^9/L$ or less^{8,10,12} (absolute neutrophil count = total leukocyte count per microliter \times percentage of neutrophils and bands $\times 0.001$). In addition, 20 children with an absolute neutrophil count of $1.5 \times 10^9/L$ or less were prospectively identified by daily review of hematology records from either the pediatric outpatient (the primary care unit and emergency department) or the inpatient (wards and intensive care unit) services. Complete blood cell counts were performed on one of two cell counters (Coulter Model S

or S-Plus, Coulter Electronics, Inc, Hialeah, Fla). Leukocyte differential counts were determined by licensed technologists who performed microscopic examinations of 100 cells on the peripheral blood smears. The medical records of all neutropenic patients were then extracted by means of a standard form to record demographic information, the clinical circumstances associated with neutropenia (ie, presenting complaints, history and physical examination findings, and initial and final diagnoses), and the clinical outcome, including the development of any infectious complication. In this study, an infectious complication was defined as a mucocutaneous or systemic bacterial or fungal infection that occurred while the patient was neutropenic. Additionally, the degree and duration of neutropenia and associated laboratory results (including blood, urine, cerebrospinal fluid, and skin cultures and bone marrow examinations) were recorded. The physicians of patients who lacked complete hospital record data on medical outcome were contacted by telephone or letter by a research assistant, for follow-up information.

Patients who were previously well and had isolated neutropenia documented during an acute, febrile illness were included. Children who had received a complete blood cell count as part of a routine screening protocol before elective surgical procedures were included as well, if they did not have a presurgical condition or syndrome known to be associated with neutropenia. Patients were also included if they had been receiving either antimicrobials for acute, self-limited common pediatric illnesses (eg, otitis media or pharyngitis) or anticonvulsants for well-defined seizure disorders and had undergone treatment at least 48 hours during the 2 weeks before the documentation of neutropenia.

Patients with a family history of a neutrophil disorder or with previously documented cyclic, autoimmune, or chronic neutropenia, pancytopenia, or chronic illnesses associated with immune suppression (eg, malignant neoplasm, human immunodeficiency virus infection, and chronic renal diseases) were excluded from the study. Patients with a serious bacterial infection (eg, meningitis or

sepsis) diagnosed at the visit when the neutropenia was detected were also excluded. Eligible patients who did not have serial white blood cell counts obtained at least every 21 days until the neutropenia resolved (as documented by a minimum of two blood counts) were analyzed separately from those in whom serial counts were available.

Data Analysis

Data were analyzed by means of a programmed calculator with standard techniques. The χ^2 test was used to analyze data that were categorical, and a χ^2 test for linearity was used for data that were part categorical and part ordinal to determine if relationships were linear.¹³ Pearson's Product-Moment Correlation coefficients were determined for dimensional data.

RESULTS

Records of 251 pediatric patients with an absolute neutrophil count of $1.5 \times 10^9/L$ or less were reviewed. Forty-three (17%) were excluded from fur-

ther analysis because of cyclic neutropenia, pancytopenia, or chronic illnesses (ie, malignant neoplasms) associated with immune suppression. Sixteen children (6%) were excluded because they presented with symptoms and signs of a serious bacterial infection (4 with meningitis, 4 with sepsis, and 8 with pneumonia) at the visit when neutropenia was detected. An additional 73 children (29%) had only clinical outcomes assessed because they did not meet the criterion of having serially documented white blood cell counts; 40 were taking medications known to be associated with neutropenia (mostly antibiotics and anticonvulsants), and 33 had acute illnesses. None of the children in these latter two groups developed an infectious complication at follow-up evaluations. The remaining 119 neutropenic patients had serial white blood cell counts documented for at least every 21 days until the neutropenia resolved, and they form the basis of this report. Sixty-six percent were acutely ill, in 15% neutropenia was detected during routine preoperative screening, and 19% were receiving antimicrobial or anticonvulsant medications known to be associated with neutropenia (Table 1). Thirty-eight percent of the acutely ill patients were initially admitted to the hospital for observation and/or antimicrobial therapy.

The mean age of the 119 patients was 42 ± 28 months, 57% were male, and 52% were white. The mean white blood cell count was $6.337 \pm 2.959 \times 10^9/L$, and the mean absolute neutrophil count was $1.029 \pm 0.498 \times 10^9/L$. Fifty-three percent of the sample had an absolute neutrophil count between 1.01 and $1.5 \times 10^9/L$, 34% between 0.501 and $1.0 \times 10^9/L$, and 13% $0.5 \times 10^9/L$ or less. The median duration of neutropenia for the entire sample was 13 days (range, 1

to 491 days), and the median duration of neutropenia for children with an absolute neutrophil count of 0.5×10^9 or less was 17 days. Neutropenia resolved in 70% of the children by 30 days and in 80% by 42 days. The median percentage of lymphocytes in the peripheral blood of the patients was 0.68 (range, 0.30 to 0.96; mean, 66.4 ± 12.4). The median percentage of monocytes was 0.08 (range, 0.01 to 0.23; mean, 7.5 ± 5.4), and of eosinophils, 0.3 (range, 0 to 0.27; mean, 2.8 ± 2.5). Eleven percent of the children had increased numbers of basophils, myelocytes, metamyelocytes, and plasmacytoid cells in the peripheral smear. Bone marrow examinations were performed in four patients; two had normal marrow cellularity, and the other two had maturation arrest at the promyelocyte or myelocyte stages. There were no racial differences among patients regarding the total leukocyte count, the initial or lowest documented absolute neutrophil count, the duration of neutropenia, or the proportions of lymphocytes, monocytes, or eosinophils. In addition, no correlation was found between the initial absolute neutrophil count and the duration of neutropenia in either white ($r = .185$, $P = .15$) or black ($r = .156$, $P = .20$) ($r_{\text{total}} = .163$, $P = .10$) children.

Four children (3.4%) developed documented infectious complications while they remained neutropenic, all for longer than 30 days (Table 2). No patient had an absolute neutrophil count of $0.5 \times 10^9/L$ or less when an infectious complication was diagnosed. In addition, the documented nadir of the neutrophil count was not correlated with the time of onset of an infectious complication in any of these patients. All of the patients were hospitalized, but none experienced severe morbidity from the infectious complication. Three were

*ANC indicates absolute neutrophil count; IC, infectious complication.

treated with antimicrobials administered intravenously. All patients improved within 4 to 8 days of hospitalization, and in two cases complete clinical recovery occurred before resolution of neutropenia. No bacterial, fungal, or viral organisms were identified by blood, cerebrospinal fluid, or tissue cultures in any of these children. The absolute neutrophil count rose to over $1.5 \times 10^9/L$ in these patients within 1 to 12 days after diagnosis. None of the children redeveloped documented neutropenia in the several months after the infection. Furthermore, no significant associations between the development of an infectious complication and either the initial ($\chi^2=1.36$, $P=.25$) or lowest ($\chi^2=3.50$, $P=.08$) documented absolute neutrophil count were found.

COMMENT

This study has documented that otherwise healthy children in whom isolated, transient neutropenia is discovered during a minor, acute illness, routine preoperative screening, or treatment for common pediatric conditions are at little risk of developing septicemia or other serious infectious complications. In addition, infections are infrequent, occur in children with neutropenia lasting longer than 30 days, and tend to be superficial (ie, involve the skin and mucous membranes) in a majority of cases. None of these patients developed septicemia or bone or central nervous system infection.

It is fairly common for a pediatrician to encounter a child with isolated, transient neutropenia in many clinical settings. A retrospective review by Bowden et al¹⁴ demonstrated that neutropenia was present in 3% of inpatients and 7% of outpatients. Although one third of our patients had an absolute neutrophil count between 0.5 and $1.0 \times 10^9/L$, documented cases of stomatitis, gingivitis, or skin infections did not occur with the frequency that has been previously reported with counts in this range.¹¹ More importantly, only one of the 16 previously well children with initially severe neutropenia (absolute neutrophil counts $<0.5 \times 10^9/L$) experienced any infectious complication. This patient developed stomatitis after a prolonged period of neutropenia. Valiaveedan et al¹⁶ recently reported on an

almost identical number of patients with severe neutropenia and found bacteremia from commonly identified organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*) in three patients. The reasons for the relatively high proportion of children with bacteremia, although not discussed, perhaps were related to patient selection, since all of their patients had been hospitalized and evaluated by the hematology service. Combining cases of our series and that of Valiaveedan et al, none of the 33 children with an absolute neutrophil count less than $0.5 \times 10^9/L$ had invasive infections with either *Staphylococcus* or gram-negative enteric organisms as are commonly encountered in immunosuppressed patients with severe neutropenia.¹⁰

One half of the patients in our series were black, suggesting that possibly some had "pseudoneutropenia" or "benign neutropenia." This phenomenon has been identified in a proportion of the 20% to 30% of blacks with a significantly lower mean total white blood cell count than whites.¹⁶⁻¹⁸ However, the distribution of the absolute neutrophil count in black children in our series paralleled that of white children, and the duration of neutropenia in both black and white children was similarly transient and consistent with a previous report.¹⁵ In addition, all of the black children had an absolute neutrophil count greater than $1.5 \times 10^9/L$ at follow-up determinations. Therefore, black children with transient neutropenia do not appear to be at any different risk for the development of serious infections than are white children. The question of whether there is a subset of black children with an absolute neutrophil count chronically in the neutropenic range and thus at potential risk for serious infections is not addressed by this study.

There are certain limitations of this study that may affect the interpretation of the data. The timing of serial blood counts was usually up to the discretion of the patient's physician. Therefore, the precise duration of neutropenia for any given patient is unknown. However, a median duration of neutropenia of 13 days clearly indicates that it was transient in a large number of cases. While there did not appear to be any relationship between the subsequent

development of an infectious complication and either the initial or lowest absolute neutrophil count, the number of patients with severe neutropenia was small and the duration of neutropenia relatively transient. It is possible that this degree of neutropenia is not commonly detected in essentially well children.

The mechanisms by which many acute childhood illnesses (eg, parvovirus infection) induce transient neutropenia are incompletely understood. It is postulated that neutropenia in these situations may be the result of a number of processes, including excessive neutrophil margination along endothelial surfaces, complement activation of C5 to C5a, an increase in the peripheral utilization or destruction of leukocytes, endotoxin depletion of the bone marrow reserve pool, or suppression of myelopoiesis by the infecting agent.^{8,10-12} Another possible mechanism for the induction of neutropenia is a transient production of circulating antineutrophil autoantibodies.^{6,19} Both toxic and immunologic mechanisms for drug-induced neutropenia have been described in detail elsewhere.^{11,20,21}

Overall, the small number of patients experiencing an infectious complication paralleled previously reported patterns of skin, mucous membrane, and pulmonary infections seen in children with other forms of neutropenia.^{4,19} The four patients with complications had benign courses and had normal neutrophil counts within 2 weeks of the onset of complications. The recovery from neutropenia may have been coincidental with the infection or related to such factors as waning antineutrophil antibodies or a direct effect of the infection in stimulating the bone marrow. The majority of patients in this sample had an increase in the mean proportion of lymphocytes, monocytes, or eosinophils, often in ranges that were greater than expected for age.¹² Whether the increase in circulating lymphocytes and other granulocytes had a protective effect against invasion of microorganisms is unknown. The commonly encountered peripheral-blood monocytosis in many neutropenic states may offer only nominal protection against pyogenic organisms, since the response of monocytes to chemotactic stimuli and their

rate of phagocytosis are more sluggish than are those of polymorphonuclear leukocytes.²²

The clinical implication for practitioners is that otherwise well children with neutropenia are unlikely to develop serious infectious complications, especial-

ly if the neutropenia is transient. In most cases, these patients do not require an extensive laboratory evaluation to identify potential pathogens and/or institution of empiric antimicrobial therapy, as has been suggested by some authors.^{10,23} Instead, diligent ob-

servation and frequent follow-up are probably quite efficient courses of management for these patients.

Pulmonary Hypertension and Asthma in Two Patients With Congenital Heart Disease

Abraham Rothman, MD, Thomas J. Kulik, MD

• **Reactive airway disease has only rarely been associated with pulmonary hypertension. We treated two patients with congenital heart disease and asthma who had increased pulmonary arterial pressure at cardiac catheterization. Pulmonary hypertension could not be explained solely by the cardiac lesion, nor by respiratory mechanical factors, as the patients did not have wheezing during the catheterization study. After long-term treatment with bronchodilators, corticosteroids, and oxygen, and coincident with improvement in the airway disease, there was catheterization-proved diminution of pulmonary hypertension. Whether asthma and pulmonary hypertension were causally linked is unknown, but further work seems indicated to elucidate the relationship between bronchoconstriction and pulmonary vasoconstriction. Furthermore, aggressive management of even mild reactive airway disease may be warranted in patients with pulmonary hypertension, regardless of apparent cause.**

(AJDC. 1989;143:977-979)

Pulmonary hypertension and cor pulmonale are common sequelae in patients with severe chronic obstructive lung disease, upper airway obstruction, and bronchopulmonary dysplasia.^{1,2} However, pulmonary hypertension has rarely been described in association with asthma. There are a few case reports of the association of pulmonary hypertension and reactive airway disease in adults³⁻⁵ and children,^{6,7} but most of the patients had moderate to severe hypoxemia or polycythemia. In this article, we describe two patients with congenital heart disease, pulmonary hypertension, and asthma but no significant hypoxemia, acidosis, or polycythemia.

Pulmonary hypertension was documented when the patients did not have significant wheezing but were in a period of their lives when they were having significant asthmatic attacks. With long-term treatment for and amelioration of their airway disease, they had a catheterization-proved decrease in pulmonary arterial pressure.

PATIENT REPORT

PATIENT 1.—A male patient with pulmonary atresia, malalignment ventricular septal defect, and multiple aortopulmonary collaterals underwent placement of a right ventricular to pulmonary arterial valved homograft, patch closure of the ventricular septal defect, and coil embolization of the aortopulmonary collaterals at 16 months of age. Postoperative catheterization (1 month later, to coil another aortopulmonary collateral) revealed a pulmonary arterial pressure of 30/10 mm Hg (one third of systemic pressure). On routine follow-up recatheterization at 26 months of age, he had suprasystemic pulmonary arterial pressure unresponsive to 100% oxygen (Table). The pulmonary arteries were large and without evidence of peripheral stenosis. When catheterized, he did not have significant cyanosis, coughing, wheezing, or respiratory distress. A chest roentgenogram showed moderate cardiomegaly and hyperinflation but no edema or infiltrates.

During the next 4 months he was admitted to the hospital three times in status asthmaticus, twice requiring endotracheal intubation. The wheezing and respiratory distress responded to intravenous isoproterenol hydrochloride, theophylline, and corticosteroids. In the following year he was treated at home with oxygen, albuterol, metaproterenol sulfate, theophylline, cromolyn sodium, and corticosteroids. He had virtual resolution of his airway disease, and all drugs, except oral albuterol, were stopped by 40 months of age. He was recatheterized at 45 months of age, and the pulmonary arterial pressure had decreased to nearly normal levels (Table).

PATIENT 2.—A male patient with double inlet left ventricle, subaortic outflow cham-

ber, restrictive bulboventricular foramen, and severe tubular hypoplasia of the aortic arch underwent a main pulmonary artery to ascending aorta anastomosis (to provide unobstructed outflow from the ventricle to the aorta), ascending to descending aorta homograft, and a modified right Blalock-Taussig shunt (4-mm polytetrafluoroethylene; Impra) graft from the right subclavian artery to the right pulmonary artery) at 6 days of age. Because of increasing cyanosis, at 9 months of age he was recatheterized, and the mean pulmonary arterial pressure was 10 mm Hg. He then underwent a Glenn anastomosis (the pulmonary arteries were divided near their confluence, the superior vena cava was anastomosed to the right pulmonary artery, and the shunt was left in continuity with the left pulmonary artery).

At 11 months of age he was admitted to the hospital with respiratory distress and facial edema. The chest roentgenogram revealed a normal heart size, a small right pleural effusion, increased pulmonary venous markings, and no evidence of air trapping. At catheterization, he did not have a significant cough or wheezing. He had an elevated right pulmonary arterial pressure, a mean left atrial pressure of 9 mm Hg, and a mean right atrial pressure of 6 mm Hg (Table). Although the left atrial pressure was within normal limits, a blade and balloon atrial septostomy was performed to decrease the pulmonary arterial pressure by lowering the left atrial pressure. Despite lowering the mean left atrial pressure to 6 mm Hg, the mean pulmonary arterial pressure decreased only to 21 mm Hg. Later during that hospitalization, the patient developed wheezing, which responded to metaproterenol, cromolyn, and oxygen. He was discharged from the hospital receiving nebulized metaproterenol and cromolyn and did not have any more episodes of significant wheezing.

At recatheterization at 14 months of age, the pulmonary arterial pressure had decreased to a mean of 13 mm Hg (Table).

COMMENT

Although pulmonary hypertension and cor pulmonale have been documented during acute asthmatic episodes,³⁻⁸ pulmonary hypertension seems

to be infrequent during chronic stable asthma. One report⁶ described three children seen in Denver, Colo, with acute signs and symptoms of asthma, moderate arterial hypoxemia, and catheterization-proved pulmonary hypertension. One of the children died and the other two improved symptomatically (one after moving to a lower altitude), but there was no documentation of reversal of pulmonary hypertension.

In this article, we describe two young patients with congenital heart disease and elevated pulmonary arterial pressure out of proportion to their cardiac defect and age. Pulmonary hypertension was documented at a catheterization when they had no significant wheezing but in a period of their lives when they had significant acute asthmatic attacks. Both patients had documentation of low pulmonary arterial pressure by a previous catheterization, making it even more unlikely that the pulmonary hypertension was linked to the cardiac defect. Other causes of pulmonary hypertension were ruled out; chest roentgenograms did not show evidence of significant lung disease, such as pneumonia or atelectasis. Neither patient had significant respiratory distress when catheterized, minimizing the possibility of significant mechanical effects, such as large swings in intrathoracic pressure.⁹ They did not have sig-

nificantly elevated left atrial pressure or signs of congestive heart failure and, therefore, did not have "cardiac" asthma, nor did they have significant acidosis, hypercapnia, or polycythemia. They did have variable degrees of systemic arterial oxygen desaturation, but only mild pulmonary venous desaturation (Table). However, even after the pulmonary venous saturation was increased acutely with oxygen in patient 1, the pulmonary vascular resistance did not decrease significantly. Even though these patients did not have significant wheezing when catheterized, patient 1 had episodes of status asthmaticus within a month of the procedure, and patient 2 developed wheezing during that hospitalization and required bronchodilator treatment after discharge from the hospital. Both patients had a strong family history of asthma.

The coexistence of pulmonary hypertension and bronchoreactive airway disease raises several possibilities. First, it is possible that the pulmonary hypertension and asthma were fortuitously and not functionally associated. However, spontaneous resolution of pulmonary hypertension outside the newborn period is exceedingly rare.¹⁰ There was no intervening surgical or catheterization procedure to cause the decrease in pulmonary arterial pressure. Furthermore, the treatment given for asthma

did not include any conventional drugs used to treat pulmonary hypertension. However, an effect by these agents on the pulmonary vasculature cannot be ruled out, since it has been shown that aminophylline¹¹ and cromolyn¹² can inhibit hypoxic pulmonary vasoconstriction, and long-term oxygen therapy was beneficial to patients with pulmonary hypertension and chronic obstructive lung disease.¹³

Alternatively, the pulmonary hypertension and asthma may have been functionally associated, especially since they occurred simultaneously, and the decrease in pulmonary arterial pressure was concomitant with improvement in the airway disease. Since both bronchi and pulmonary vessels contain smooth muscle in their walls and are in close anatomic relation, release of mediators that cause both bronchoconstriction and vasoconstriction may be involved. Among these potential mediators are histamine,^{14,15} prostaglandin D₂,^{16,17} prostaglandin F_{2α} and thromboxane A₂,^{18,19} and leukotrienes C₄ and D₄.¹⁵ Indeed, pulmonary vasoconstriction and bronchoconstriction are known to be temporally associated and possibly caused by the same mediator(s) in patients with pulmonary thromboembolism.²⁰ In further support of this association between bronchial and vascular disease is a report of 10 adult patients with idiopathic

pulmonary hypertension, 8 of whom had decreased airflow on pulmonary function tests.²¹ Although the fact that our patients were not wheezing when they were catheterized might argue against this possible association, differential bronchial and vascular smooth-muscle sensitivity to the mediators and proximity to the site of release might explain the differing bronchial and vascular responses at a certain point in time.

A third possibility is that there are

individuals with hyperreactive bronchial and vascular smooth muscle, who will abnormally respond to "normal" levels of circulating agents or triggering stimuli with bronchoconstriction and vasoconstriction. One report described a group of patients with concomitant systemic and pulmonary arterial hypertension, raising the possibility of a common mediator or shared hyperreactivity of two different smooth-muscle cell tissues.²² There is also evidence that

smooth-muscle hyperreactivity is an important component in the pathogenesis of essential hypertension.²³

Although this report does not establish a causal relationship between asthma and pulmonary hypertension, it does suggest that this association should be sought in other patients with a similar presentation. Furthermore, aggressive treatment of even mild reactive airway disease may be indicated in patients with pulmonary hypertension.

Hormonal Therapy for Cryptorchidism With a Combination of Human Chorionic Gonadotropin and Follicle-Stimulating Hormone

Success and Relapse Rate

Giuseppe Saggese, MD; Paolo Ghirri, MD; Stefano Gabrielli, MD; Giulio C. M. Cosenza, MD

• We treated 163 patients (Tanner stage I), aged 1 to 11 years, with cryptorchidism with a combination of 500 to 2000 IU of human chorionic gonadotropin divided into two intramuscular injections and given weekly and 75 IU of follicle-stimulating hormone once a week for 6 weeks. One hundred twelve patients had unilateral cryptorchidism. Response to therapy, which is descent of testes into scrotum, by age group was as follows: 2 (13.3%) of 15 patients aged 1 to 2 years; 8 (29.6%) of 27 patients aged 3 to 4 years; 13 (38.2%) of 34 patients aged 5 to 6 years; and 18 (50%) of 36 patients aged 7 to 11 years. Fifty-one patients had bilateral cryptorchidism. Response by age group was as follows: 1 (16.6%) of 6 patients aged 1 to 2 years; 3 (27.2%) of 11 patients aged 3 to 4 years; 6 (37.5%) of 16 (plus unilateral descent in 1 patient) aged 5 to 6 years; and 10 (55.5%) of 18 patients aged 7 to 11 years. The results are comparable with those obtained with human chorionic gonadotropin treatment alone. A relapse rate of 9.7% after 18 months of follow-up seemed to be lower compared with those reported with treatment with gonadotropin-releasing hormone or treatment with human chorionic gonadotropin alone.

(AJDC. 1989;143:980-982)

Cryptorchidism is found in 3% to 4% of full-term newborn infants. This figure for the physiologic phenomenon of late spontaneous migration, which is probably due to the testosterone rise in the first 3 months of life,¹ falls to about 1% at 1 year of age and does not change

in the years that follow.² At any rate, a periodic reexamination of the scrotum is necessary throughout a patient's childhood to document testicular reascent.³ It has been recently stressed that the testes should descend into the scrotum at an early age because after 2 years of age degeneration of the germinal epithelium with loss of spermatogonia of undescended testes has already been demonstrated,^{4,5} even if the real effectiveness of an early successful treatment in preventing later infertility^{6,7} must be proved. Nevertheless, before age 4 years the conventional hormonal treatment with human chorionic gonadotropin (HCG) is of limited usefulness,^{8,9} and treatment with intranasal gonadotropin-releasing hormone presents a high relapse rate independent of the patient's age.¹⁰ Moreover, an early orchiopey may be associated with an increased risk of testis atrophy.¹¹ Follicle-stimulating hormone (FSH) seems to play a role in testicular descent probably by enhancing luteinizing receptors in Leydig's cells and increasing intratesticular testosterone levels.¹²⁻¹⁸ Our study reports the results of using HCG and FSH together in the treatment of cryptorchidism and 18 months' follow-up data of the patients who had had descent of the testes into the scrotum at the end of treatment.

PATIENTS AND METHODS

We treated 163 boys aged 12 months to 11 years. All of them had true unilateral or bilateral cryptorchidism with intra-abdominal (nonpalpable), inguinal (palpable), or pre-scrotal testes. Patients with retractile testes, ectopic testes, anorchia, gonadotropin

deficiency, partial androgen resistance, testicular dysgenesis, and other endocrine or anatomic anomalies were excluded. All the children were prepubertal (Tanner stage P1¹⁹). Of the 163 children, 112 had unilateral cryptorchidism (65 on the right, 47 on the left) and 51 had bilateral cryptorchidism for a total of 214 retained testes. The children were divided into four groups according to age (1 to 2, 3 to 4, 5 to 6, and 7 to 11 years). Written informed consent was obtained. Each subject was treated with a combination of HCG and FSH (either human menopausal gonadotropin [HMG] or purified FSH) according to the following posologic schedule: 500 IU of HCG plus 75 IU of FSH per week (for 6 weeks) for patients younger than 2 years of age; 1000 IU of HCG plus 75 IU of FSH per week (for 6 weeks) for patients between the ages of 2 through 6 years; and 2000 IU of HCG plus 75 IU of FSH per week (for 6 weeks) for patients older than 6 years. The weekly dose of HCG was administered in two intramuscular injections—FSH once a week in combination with HCG. Purified FSH only was used in the group of children 1 to 2 years of age; no difference between the response to HMG or purified FSH was observed in the other age groups.

Once a week for 6 weeks, each child was seen and the position of the testes and side effects were recorded. The results of hormonal treatment were clinically evaluated at the end of the treatment and 4 months later to exclude temporarily positive results. The patients in whom the therapy was successful were also evaluated 18 months after the end of the treatment. When responses were not successful, a surgical correction followed. Statistical analysis was carried out using a χ^2 test.

RESULTS

By associating HCG and FSH, a complete descent at the end of treatment was noted in 36.6% of unilateral and in

Treatment of Cryptorchidism With Human Chorionic Gonadotropin and Follicle-Stimulating Hormone*

	Unilateral Cryptorchidism (n = 112)					Bilateral Cryptorchidism (n = 51)				
	Group by Age, y					Group by Age, y				
	Total	1-2	3-4	5-6	7-11	Total	1-2	3-4	5-6	7-11
At the end of treatment	36.6	13.3	29.6	38.2	50	39.2	16.6	27.2	37.5	55.5
After 4 mo	33.9	6.6	29.6	38.2	44.4	35.2	16.6	18.1	37.5	50
After 18 mo	33	6.6	25.9	38.2	44.4	35.2	16.6	18.1	37.5	50

*Values are expressed as percent of mean success rate.

39.2% of bilateral cryptorchid testes (Table). This difference was statistically insignificant. Altogether, 82 (38.3%) of 214 testes descended into the scrotum, 3 (13%) of 23 were testes not palpable before the treatment, 66 (37.3%) of 177 were inguinal palpable testes, and 13 (92.8%) of 14 were testes located at the scrotal neck. Among inguinal palpable testes the results were better in that they could be brought into the scrotum or to the scrotal neck. Twenty-nine testes (13.5%) improved their position but did not descend completely, and 103 testes (48.1%) did not respond to the treatment.

There was no different response to therapy between right-sided or left-sided cryptorchid testes. Four months after the end of therapy, relapses occurred in 8.5% (7/82) of the testes (3 patients with unilateral cryptorchidism and 3 patients with bilateral cryptorchidism—1 showed bilateral relapse, and 2 patients showed unilateral relapse, 1 of which occurred after unilateral descent) in which the therapy was successful and the success rate dropped to 33.9% of unilateral and 35.2% of bilateral cases (Table). After 18 months of follow-up, recurrences were found in another patient (who had unilateral cryptorchidism) (relapse rate: 9.7%, 8 of 82 testes) with a further reduction in the success rate of unilateral cryptorchid testes (33%) (Table).

The best results were obtained in children older than 6 years of age with both unilateral (50% at the end of therapy, 44.4% after 18 months) and bilateral (55.5% at the end of treatment, 50% after 18 months) cryptorchidism (Table). In the group of children 5 to 6 years of age, complete descent was observed in about one third of the patients (unilat-

eral, 38.2%; bilateral, 37.5%). In the group of children 3 to 4 years old, complete descent was noted in 29.6% of children with unilateral cryptorchidism (one relapse occurred after 18 months and success rate was 25.9%), and of 27.2% of bilateral cryptorchid testes, there was one relapse after 4 months—a success rate after 18 months of 18.1%. In the group of children 1 to 2 years of age, only 2 patients with unilateral (13.8%) and 1 patient with bilateral (16.6%) cryptorchid testes have had complete descent into the scrotum. One patient with unilateral cryptorchidism had the relapse after 4 months and, therefore, the success rate dropped to 6.6%. Slight side effects were noted and included a small increase in the size of the penis in 22 children (13.5%), spontaneous erections in 14 children (8.6%), and irritability during the treatment in 7 children (4.3%).

COMMENT

Experimental and clinical data suggest that FSH can play an important role in modulating the testosterone secretion of the testes. Follicle-stimulating hormone probably plays the role of increasing luteinizing hormone receptor density in Leydig's cells and stimulating the secretion rate of androgen-binding protein by Sertoli's cells with accumulation of intratesticular testosterone.¹²⁻¹⁸

Our results with combined hormonal therapy (HCG and FSH) are quite similar to those found in studies on the use of this association²¹⁻²² and also to those obtained by using HCG alone.^{8,23-26} Moreover, it is difficult to compare the results of different studies for the variation in dosages, the differences in the selection of patients, and the lack of follow-up data.

Apart from the problem of the insertion of retractile testes in our series, an important aspect to be considered is the position of the testes before the treatment. The worst results are obtained in abdominal retention, as can be seen in the patients in our study. Very good results are obtained in inguinal position, and even better results are obtained in prescrotal position with complete descent in 92% to 99% of the patients.^{23,28} Moreover, it has been noted that among the inguinal palpable testes, the more mobile they are (that is, the ones that could be brought into the scrotum or just above it), the better they respond to the treatment.²⁶ In reference to the therapeutic failures according to Bierich,²⁹ the operation in our patients pointed out ectopia that were not clinically seen before in about 20% of the patients with cryptorchidism.

Our findings emphasize that it is difficult to detect ectopia in all of the patients before treatment, and many patients appear to be unresponsive to hormonal treatment for this reason. Another important factor is the unilateral or bilateral form of cryptorchidism. From our data it can be said that good results were obtained both in unilateral and bilateral cases, even if a slightly higher percentage of success was noted in the latter. However, the difference is not significant. Our data demonstrate that in patients with unilateral and bilateral cryptorchidism, better results were obtained in older children (older than 6 years of age). However, recent studies^{4,6} have shown that histological damages with reduction in the number of spermatogonia have even appeared in 2-year-old patients. It is clearly unnecessary to treat these children earlier.

Nevertheless, by evaluating the results obtained in the group of children 1 to 2 years of age, the success rate after 18 months of follow-up was only 6.6% in cases of unilateral and 16.6% in cases of bilateral cryptorchidism. Therefore, the combination of HCG and FSH seems no more effective than HCG alone in patients younger than 3 years of age,⁶ and it is of limited usefulness in producing testicular descent in the group of patients who are 1 to 2 years of age to facilitate optimum potential for fertility.

An important problem to be consid-

ered is the relapse rate after successful therapy. Reevaluations of the success rate 6 to 12 months after the end of the treatment with HCG are generally lacking. Bierich²⁷ reported a relapse rate 6 months after the treatment of about 30% in all his series and of 40% to 50% between 0 and 10 years of age. The same or higher percentage of relapses was seen after gonadotropin-releasing hormone therapy.^{18,28-30} Combined therapy with gonadotropin-releasing hormone and HCG was able to reduce the recurrence rate to about 10% after 6 months,^{17,18} and our relapse rate with combination therapy of HCG and FSH was only 9.7% after 18 months of follow-up. Gonadotropin-releasing hormone probably induced FSH stimulation. Follicle-stimulating hormone adminis-

tration may also increase responsiveness to luteinizing hormone-enhancing luteinizing hormone receptor population in Leydig's cells or the amount of Leydig's cells recruited from fibroblasts.^{12-14,18} Follicle-stimulating hormone also stimulates the formation rate of androgen-binding protein, which will increase intratesticular testosterone levels.^{14,15} If testicular descent occurs, however, even though it may be transient, it can be predicted that permanent descent will occur at puberty.³¹

In conclusion, our data showed that the combination therapy of HCG and FSH provided good results in the treatment of cryptorchidism without any important side effects. In patients younger than 3 years of age it is ineffective. At present the best age for the combina-

tion treatment of HCG and FSH seems to be in patients who are 3 to 4 years old. This is a compromise between the histological alterations that do not seem serious and a better response to the therapy at this age. Of course, only the follow-up of these patients treated earlier with the combined therapy will be able to confirm if an improvement of fertility can be obtained. The relapse rate after a follow-up of 18 months was only 9.7% of the testes in which the therapy was successful after 6 weeks. The evaluation of the overall results 4 months after the end of the treatment practically rules out only temporarily positive results, even if the follow-up must be carried out much later to guard against the possibility of a late relapse.

Neonatal Hyperbilirubinemia at High Altitude

Cynthia Leibson, PhD; Mark Brown, MD; Steve Thibodeau, PhD; David Stevenson, MD; Hendrik Vreman, PhD; Ron Cohen, MD; Gisela Clemons, PhD; Wayne Callen, MD; Lorna Grindlay Moore, PhD

• A previous retrospective study showed an increased frequency of neonatal hyperbilirubinemia at high altitude in Colorado. In a prospective study we found that 39% of newborns at 3100 m altitude vs 16% at 1600 m exhibited hyperbilirubinemia, defined as a day 3 serum bilirubin level of 205 $\mu\text{mol/L}$ or higher. Increased bilirubin production at 3100 m vs 1600 m was shown by increased levels of corrected carboxyhemoglobin. This finding was supported by increased erythropoietin and bilirubin values in cord blood and increased hematocrit values at day 3 among infants at 3100 m vs 1600 m. The sustained elevation in bilirubin for breast-fed vs formula-fed infants at 1600 m was observed for both feeding types at 3100 m. The findings suggested that there is a hematologic response to decreased oxygen availability at high altitude, resulting in increased bilirubin production accompanied by delayed bilirubin clearance.

(AJDC. 1989;143:983-987)

We observed an increased frequency of neonatal hyperbilirubinemia at higher (3100 m) compared with lower (1600 m) altitude in Colorado in a previous retrospective study.¹ In the present study we compared infants born at 1600 m and 3100 m to determine whether this finding could be confirmed prospectively. If so, we sought to determine the extent to which increased bilirubin production and/or decreased capacity

for clearance were operating at the higher altitude. We considered that an understanding of factors responsible for the increased frequency of hyperbilirubinemia at 3100 m might be informative as to how the transition from fetal to neonatal life was influenced by the reduced oxygen availability of high altitude, as well as to the understanding of neonatal hyperbilirubinemia generally.

SUBJECTS AND METHODS

Subjects

Subjects born at lower altitudes consisted of infants born over a study period of 19 nonconsecutive weeks at Children's Hospital/St Luke's, Denver, Colo, at an elevation of 1600 m. Subjects born at higher altitudes consisted of infants born over a 10-month period at St Vincent Hospital, Leadville, Colo, at an elevation of 3100 m. White, singleton, full-term healthy infants whose parents granted consent were eligible for the study. Full-term births were defined as gestational age between 38 and 41 weeks from The onset of the mother's last menstrual period. Infants were considered healthy when their 5-minute Apgar score was 8 or higher and when their newborn course was uncomplicated by respiratory distress, congenital abnormality, sepsis, or any other conditions requiring transfer from the low-risk nursery. Infants with positive results of either direct or indirect Coombs' test indicative of Rh or blood group incompatibility were excluded. The parents of two infants at each altitude declined consent.

A major part of the analysis involved the comparison of day 3 serum values between the two altitudes. For some of the 58 eligible infants at 1600 m and the 45 eligible infants at 3100 m we were unable to obtain a mean (\pm SEM) blood serum value at 72 ± 12 hours drawn in conjunction with the required phenylketonuria testing, either because of scheduling conflicts ($n=6$ at 1600 m; $n=7$ at 3100 m) or insufficient serum sample ($n=3$ at 1600 m; $n=7$ at 3100 m). Data analysis with these infants, using serum values from day 2 or day 4 and transcutaneous values when no serum was available, gave the same results as analysis without these infants. However,

to assure comparability of the study groups, infants from whom no serum sample was available at 72 ± 12 hours were excluded from the final analysis, yielding a sample size of 41 breast-fed and 8 formula-fed infants at 1600 m and 21 breast-fed and 10 formula-fed infants at 3100 m. Infants at 3100 m received supplemental 24% O_2 before being weaned to room air (mean, 17 ± 3 hours; range, 2 to 120 hours). Infants at both altitudes were followed up by one of us (C.L.). Study procedures were approved by the University of Colorado, St Vincent Hospital, and Children's Hospital Human Subjects Review Committees.

Relevant information on all infants was obtained from medical record review, interview, and measurement and included the following: (1) maternal characteristics: age, education, marital status, gravidity, parity, prenatal events, history of diabetes, history of smoking, blood type, labor and delivery complications, method of delivery, and use and type of obstetric anesthesia; and (2) infant characteristics: blood type, gestational age by date and by physical examination,² Apgar scores at 1 and 5 minutes, birth weight and length, head circumference, presence or absence of bruising, feeding type, frequency of feeds and supplementation, time of first bowel movement and frequency of bowel movement, weight at days 1, 3, and 7, length of hospital stay, and daily exposure to sunlight (on a five-point scale ranging from dark room/no outings to crib by the window/one or more outings).

Methods

Measurements were obtained on cord blood samples for levels of plasma bilirubin, erythropoietin and hematocrit values. Heel capillary blood samples were obtained³ at 72 ± 12 hours (mean, 70.2 ± 0.5 hours at 1600 m and 70.2 ± 1.0 hours at 3100 m) for measurement of serum bilirubin levels, hematocrit values, and carboxyhemoglobin levels. Samples were analyzed for both total and conjugated bilirubin according to the modified Jendrassik-Grof method⁴ using a centrifugal analyzer (Cobas-Bio, Roche Diagnostics, Nutley, NJ) in the same laboratory at Children's Hospital. Samples from Denver infants and day 3 samples from Leadville infants were stored in the dark at 4°C and

were analyzed within 12 hours of collection. Leadville cord samples were stored at -25°C and were analyzed within 5 days of collection. Samples kept at 4°C for 12 hours were compared with a portion of the same samples stored at -25°C for 5 days and were found to agree well (mean \pm SEM of differences in 19 samples, $0.34 \pm 1.37 \mu\text{mol/L}$; not significant). So that two infants at 1600 m and one infant at 3100 m who underwent phototherapy outside of 72 ± 12 hours were not excluded, the last available bilirubin value before phototherapy was used for these infants.

For nine of the infants in the higher-altitude group, we were unable to collect sufficient serum for bilirubin analysis by the modified Jendrassik-Grof method, and total bilirubin values were determined using the ultramicro spectral method⁶ (American Optical Bilirubinometer, Southbridge, Mass). Spectral values were converted to the equivalent Jendrassik-Grof value with a linear regression equation determined from 28 separate newborn samples analyzed with both the Jendrassik-Grof (y) and spectral methods (x) ($y = 0.944x + 17$; $P = .000$; $S_{y,x} = 8.8$; 95% confidence interval = 0.899, 0.989; 90% prediction interval at $x_{190} = 180 \pm 213$).

Transcutaneous bilirubin measurements were made on days 1, 2, 3, 5, 7, and 14 using the Minolta Jaundice Meter 101 (Air Shields, Hatboro, Pa). Transcutaneous meter readings were highly reproducible (mean \pm SEM of differences between first and second measurements = 0.46 ± 0.09 U; not significant). The meter was calibrated at both lower and higher altitudes by comparing day 3 transcutaneous and serum bilirubin values obtained simultaneously from each infant ($y = 0.9x + 125$; $r = .94$). Six infants were not available for measurement because they received phototherapy (4 at 1600 m on days 3, 5, 5, and 5 and 2 infants at 3100 m on days 3 and 5). All 6 infants were breast-fed.

Hematocrit values were measured using the microcentrifuge technique.⁸ Erythropoietin level was measured by radioimmunoassay.⁶ Laboratory values for interassay and intra-assay variability for this procedure are 9.7% and 8.4%, respectively. The opportunity for carboxyhemoglobin analysis became available after the study at low altitude was nearly completed. Carboxyhemoglobin values were obtained from 8 of the infants born at 1600 m and 17 of the infants born at 3100 m. Samples were analyzed by gas chromatography in the Neonatology Metabolism Laboratory at Stanford University, Palo Alto, Calif.⁷ Blood carboxyhemoglobin values were corrected for ambient carbon monoxide levels.⁸ Ambient air samples were collected at times and locations near where the sampling for each infant was done and were analyzed by gas chromatography.

Fig 1.—Distributions of serum bilirubin values at 72 ± 12 hours in infants at altitudes of 3100 m and 1600 m. Shaded areas indicate formula-fed infants.

Statistical Analysis

Measurements were made in duplicate and the average value was recorded. Comparison of values between 1600 m and 3100 m was conducted using unpaired (Student's) t tests, Mann-Whitney U tests, and χ^2 tests. Comparison of bilirubin levels obtained from the same infant at birth and day 3 were performed using paired t tests. Relationships between variables were assessed using linear regression techniques. Results were considered significant when $P \leq .05$. Data are reported as mean \pm SEM.

RESULTS

Neonatal hyperbilirubinemia, defined as a serum bilirubin level of $205 \mu\text{mol/L}$ or higher at 72 ± 12 hours after birth, occurred in 39% (12/31) of the infants born at 3100 m, which was more than twice the 16% (8/49) incidence at 1600 m (Fig 1). The effect of altitude was most apparent in the comparison of formula-fed infants; mean day 3 and transcutaneous bilirubin values for breast-fed infants did not differ between altitudes (Table 1 and Fig 2). However, the proportion of breast-fed infants at 3100 m with bilirubin levels of $205 \mu\text{mol/L}$ or more at day 3 was 2.8 times that for breast-fed infants at 1600 m (10 of 21 at 3100 m vs 7 of 41 at 1600 m; $P < .05$).

We considered the possibility that differences in maternal smoking between altitudes, while not significant, contributed to the finding of higher bili-

Fig 2.—Median transcutaneous bilirubin values in breast-fed (top) and formula-fed (bottom) infants at altitudes of 3100 m (breast-fed infants, $n = 21$; formula-fed infants, $n = 10$) and 1600 m (breast-fed infants, $n = 41$; formula-fed infants, $n = 8$).

rubin levels among formula-fed infants at 3100 m vs 1600 m. Lower bilirubin values have been reported for infants whose mothers smoke at least one pack of cigarettes a day compared with infants of nonsmoking mothers.⁹ Comparison of formula-fed infants of nonsmoking mothers revealed bilirubin values at day 3 at 3100 m to be $180 \pm 24 \mu\text{mol/L}$ ($n = 9$) vs values at 1600 m of $127 \pm 31 \mu\text{mol/L}$ ($n = 5$; not significant). When all infants of nonsmoking mothers were considered, this difference reached significance ($181 \pm 12 \mu\text{mol/L}$ at 3100 m vs $153 \pm 11 \mu\text{mol/L}$ at 1600 m; $P = .05$). A significant association was found between bilirubin values at day 3 and altitude when adjusted for feeding type, maternal smoking, supplement, and caput/hematoma ($F[1,74] = 3.94$; $P = .05$).

Cord bilirubin values were significantly elevated in infants at 3100 m compared with infants at 1600 m (Table 1). The rise in bilirubin from birth to day 3 measured serially on the same infants was greater at 3100 m than at 1600 m (Δ bilirubin, 154 ± 12 vs $123 \pm 10 \mu\text{mol/L}$; $P < .05$). This difference was apparent when formula-fed but not breast-fed infants were compared (Fig 2). Serial transcutaneous measurements indicated that mean bilirubin values at day 7 for formula-fed infants at 3100 m ($81 \pm 23 \mu\text{mol/L}$; $n = 10$) remained signif-

icantly elevated above cord blood levels, whereas values at day 7 for formula-fed infants at 1600 m (24 ± 12 $\mu\text{mol/L}$; $n=8$) had returned to cord blood levels. Time of peak bilirubin level did not differ between altitudes. Infants at 3100 m exhibited higher carboxyhemoglobin values, higher hematocrit values at day 3, and increased erythropoietin values compared with infants at 1600 m (Table 1).

Comparison of subjects at 1600 m and 3100 m for maternal and infant characteristics showed that the study groups were similar with respect to most risk factors for neonatal hyperbilirubinemia. Values for selected characteristics, including all those for which a significant difference between altitudes was found, are presented in Table 2. As determined from review of maternal histories, none of the mothers were diabetic or exhibited gestational diabetes.

COMMENT

This prospective study confirmed the previous retrospective observation of a more than twofold increase in the proportion of infants with serum bilirubin values at day 3 of 205 $\mu\text{mol/L}$ or more at 3100 m compared with 1600 m in Colorado.¹ The increased proportion of neonatal hyperbilirubinemia was supported by higher cord blood bilirubin values at 3100 m. Infants at high risk for neonatal hyperbilirubinemia (eg, those with positive results of Coombs' test indicative of hemolytic disease and those with conditions requiring transfer from the low-risk nursery) were excluded; therefore, the reported figures may represent minimal estimates of the true frequency of neonatal hyperbilirubinemia at each altitude.

The greater rise in bilirubin values from birth to day 3, higher mean bilirubin values, and sustained elevation of bilirubin values at 3100 m vs 1600 m were observed in the comparison of formula-fed but not breast-fed infants (Table 1 and Fig 2). Although an explanation is not clearly discernible, it is possible that differences in breast-feeding practices between the nurseries may have contributed to this distinction between feeding types. The nursing staff at Children's Hospital/St Luke's (1600 m) promoted frequent breast-feeding and discouraged supplementa-

Table 1.—Comparison of Bilirubin and Hematologic Characteristics at 1600 m and 3100 m*

tion. Frequent supplementation was encouraged at St Vincent's nursery (3100 m) to prevent dehydration at the higher altitude. Several studies have suggested that there is a relationship between energy or fluid intake and neonatal jaundice.¹⁰⁻¹² The possibility that the effect of altitude on bilirubin levels was masked by greater energy or fluid intake in breast-fed infants at 3100 m relative to 1600 m is supported by the greater proportion of breast-fed infants who received supplements and the higher frequency of supplementation at 3100 m vs 1600 m, but refuted by the lower frequency of breast-feeding in breast-fed infants at 3100 m vs 1600 m (Table 2). Conclusions are limited by small sample sizes and the lack of data on fluid and energy intake in breast-fed infants.

One difference between samples that could not be controlled was the administration of supplemental O₂ to all infants at 3100 m. However, there was no correlation between bilirubin level and the length of time the infant was receiving supplemental O₂ ($r = .06$; $P = .75$). Because barometric pressure is lower at 3100 m, the inspired PO₂ with 24% O₂ at 3100 m was the same as that with room air at 1600 m.

Elevated serum bilirubin values in cord blood samples at 3100 m vs 1600 m suggested that the mechanisms responsible for the altitude-associated neonatal hyperbilirubinemia began before birth. We considered the possibility that increased bilirubin values observed at the higher altitude were a result of decreased intrauterine PO₂, leading to increased red blood cell production and in turn increased bilirubin formation. Increased red blood cell production at high altitude has been interpreted as a compensatory response acting to increase O₂ capacity and help defend arterial O₂ content.¹³ The higher hematocrit values at day 3 at 3100 m are in agreement with previous studies that suggest the possibility of increased red blood cell volume in the newborn at high altitude.¹⁴ Although higher hematocrit values at day 3 at 3100 m may have resulted from insensible fluid loss, no evidence of dehydration at the higher altitude was found when infants at 3100 m and 1600 m were compared for percent of weight gain by day 7 (Table 2). The elevated

Fig 3.—Mean (\pm SEM) carboxyhemoglobin values corrected for ambient air carbon monoxide (COHb_c) for newborns at sea level ($n = 22$), 1500 m ($n = 17$), 1600 m ($n = 8$), and 3100 m ($n = 17$).

erythropoietin levels in the high-altitude sample are consistent with the possibility that higher hematocrit values at 3100 m reflected increased red blood cell production possibly secondary to fetal or neonatal hypoxemia.^{15,16} Such an interpretation is limited by reports that increased cord blood erythropoietin level may be an acute response to the stress of labor and delivery rather than an index of the stimulus to red blood cell production in utero.^{17,18} The small number of deliveries without labor at 1600 m and 3100 m precluded comparison of erythropoietin levels in the absence of confounding effects of labor.

The most direct evidence for increased bilirubin production at high altitude was provided by increased carboxyhemoglobin levels in the samples at 3100 m. Carbon monoxide is produced as a by-product of heme catabolism in equimolar amounts with bilirubin,¹⁹ and measurement of carboxyhemoglobin has been shown to provide reliable estimates of endogenously produced carbon monoxide and bilirubin production.^{8,20,21} Supportive evidence for greater bilirubin production at higher altitude was provided by values for mean percent of saturation carboxyhemoglobin corrected for ambient air, on newborns at sea level ($0.58\% \pm 0.04\%$; $n = 22$) and at 1500 m ($0.66\% \pm 0.02\%$; $n = 17$) (Fig 3). Samples were analyzed for carboxyhemoglobin in the same laboratory as those obtained at 1600 m and 3100 m.

The association between endogenous carbon monoxide production and car-

boxyhemoglobin is dependent on certain assumptions. These include lack of variance in inspired air carbon monoxide content, diffusing capacity, alveolar ventilation, and oxygen tension.²¹ Variation in inspired carbon monoxide was controlled for by correcting for ambient carbon monoxide. Variation in diffusing capacity (perfusion mismatching or physiologic shunting) would not be expected to have influenced study results to the extent that subjects in both samples were healthy term newborns. With regard to alveolar ventilation, previous studies have suggested levels of endogenous carbon monoxide production, and therefore bilirubin production, are underestimated by measured carboxyhemoglobin values on infants with increased alveolar ventilation.⁸ We did not measure ventilation in the present study, but alveolar ventilation is typically increased at high altitude.²² To the extent that infants at 3100 m exhibited increased alveolar ventilation relative to infants at 1600 m, measured values of carboxyhemoglobin would have underestimated the true values of bilirubin production, in which case differences between altitudes would have been even greater than reported. Carboxyhemoglobin levels are also affected by O₂ tension; higher values at 3100 m might be predicted simply as a result of the reduced competition for hemoglobin binding at the higher altitude.²¹ However, if estimates of arterial O₂ tension at 3100 m (C.L., M.B., unpublished data, 1986) are compared with sea level val-

ues,^{23,24} the expected increase in carboxyhemoglobin levels at 3100 m would only be 0.13%. Thus, reduced competition for hemoglobin binding cannot account for the almost twofold increase in carboxyhemoglobin levels observed in infants at 3100 m compared with that in infants at sea level (Fig 3).

The second major source of elevated bilirubin levels in newborns is decreased capacity for clearance. Decreased capacity can result from impaired hepatic function as well as from incomplete degradation and increased enterohepatic circulation of bilirubin. The effects of hypoxemia on hepatic function, including impaired bilirubin conjugation, have been demonstrated in adults, animal models, and tissue culture.²⁵⁻²⁹

Few tests are available for measuring hepatic function or enterohepatic circulation that can be performed on healthy newborns. To the extent that time and occurrence of first bowel movement provide an index of enterohepatic circulation, similar findings for these mea-

sures at 1600 m and 3100 m did not support increased enterohepatic circulation at high altitude. Although decreased conjugating capacity may be responsible for the lower levels of conjugated bilirubin among infants at 3100 m compared with 1600 m (Table 1), no conclusions can be drawn because total assay variability at this level of measurement is high (SD, 3 $\mu\text{mol/L}$; 8.6% coefficient of variation).

Decreased capacity for clearance has been implicated as the mechanism responsible for the higher peak values and sustained elevation of bilirubin levels typically exhibited by breast-fed vs formula-fed infants.³⁰⁻³² A study by Meyers et al³³ suggested that the higher bilirubin levels observed for breast-fed vs formula-fed infants were not attributable to increased bilirubin production. Although the higher carboxyhemoglobin, erythropoietin, and hematocrit values found for infants at 3100 m relative to 1600 m are consistent with increased bilirubin production at the higher altitude, we cannot exclude the possibility

that decreased capacity for clearance may have contributed to the sustained elevation of bilirubin levels among formula-fed infants at 3100 m vs 1600 m (Fig 2).

The question of whether bilirubin values above 205 $\mu\text{mol/L}$ observed at high altitude are benign or toxic remains to be investigated. Such studies are important for determining when laboratory investigation and therapeutic intervention are appropriate at high altitude as well as for understanding the complex phenomenon of neonatal hyperbilirubinemia.

We wish to thank the physicians, nursing staff, and laboratory personnel of St Vincent Hospital and Children's Hospital/St Luke's for their involvement. We also thank Robert McCalmon, PhD, of Immunologic Associates, Denver, Colo, Leroy Heidt of the National Center for Atmospheric Research, Boulder, Colo, and Steven Arnold of the Colorado Department of Health, Denver, for technical assistance. We appreciate the helpful comments of the reviewers, Peter O'Brien, PhD, and James Naessens of the Mayo Clinic, Rochester, Minn. We also thank Steve Hofmeister and Rosann McCullough for their help in preparing the manuscript. We express thanks to the newborns and their parents who generously participated in this study.

The Pediatrics Board Review Course

September 26-October 1, 1989 Chicago

Spring and Fall 1990 — Sites to be Chosen

Now, your review and update for board exams and practice

Sponsored by the Osler Institute

OBJECTIVES:

- Improve basic and clinical knowledge in pediatrics
- Assist residents and fellows in organizing study
- Prepare candidates to take examinations
- Provide practicing pediatricians with a review and update

METHODS:

- HOME STUDY MATERIALS with a syllabus of questions and answers — and assignments
- SEMINAR with projection slides and syllabus
- PRACTICE EXAMS with oral and written parts

"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."

"Accommodations were comfortable..."

GOALS AND LOCATION: The course is held the week before oral and written board exams. Sites are chosen for excellent study and minimal cost of hotel and travel for board candidates. Home study questions will be sent before the course and answers are sent after completing your assignment. Your best value is to repeat the seminar for half price the week before your written or oral exam. The course will be held at the Holiday Inn Willowbrook, 7800 Kingery Highway, Willowbrook — 15 miles south of O'Hare and 10 miles west of Midway Airport. Rates are \$65 single and \$88 double.

"...and those little extras..."

LOWEST AIR FARES: Reliable Travel offers you the lowest air fare — often below super-saver rates. Please call toll-free 1-800-548-8185 and identify yourself with this Osler course for special group fares.

"...remarkably complete and pleasant..."

PLACEMENT SERVICE: For a practice opportunity write or call (800) 356-7537.

"...the most education for the money..."

FEES AND C.M.E. CREDITS:

- C.M.E. Credit: 60 hrs.
- Practicing Pediatrician: \$660
- Residents and Fellows: \$440
- Repeating course within 3 yrs.: half price
- Add 10% within 10 days of course.
- Attendees not in course hotel add \$8/day.
- Fees do not include lodging or meals.
- \$50.00 will reserve your position.

"...home study material was extremely helpful..."

REFUNDS: Subject to a \$50 fee, refunds will be made until the seminar begins.
• Cancellation after mailing home study material requires retention of half the fee.

"I feel [the course] helped me pass the boards..."

A Note from "Mom":

We have a son who was born prematurely, had many gastrointestinal problems and was gaining weight poorly. Your Nutramigen formula was what finally brought him around. He gained a blessed pound a week on it! Although it's expensive -- our Nathan was worth every penny & we are grateful to your company for this excellent product.

RICHARD W. GAST
PRESIDENT

... on the consumer promotion of infant formula.

There is a development that undermines your control over the infant's diet and health, and that undermines breastfeeding—the advertisement of formulas directly to the mother through TV, magazines and mail.

On June 1, the President of the American Academy of Pediatrics sent a letter to all Fellows of the Academy reaffirming its stance against consumer advertising, and expressing concern that other formula companies might follow Nestlé/Carnation.

This concern was justified. On June 15, it was announced at a press conference that Mead Johnson/Bristol-Myers will be producing an infant formula to be sold and marketed under the Gerber label. Part of the program is a multimillion-dollar budget for advertising the formula directly to mothers via TV and print.

Speaking at the press conference, Gerber Products Division President Robert L. Johnston, Jr., said that Gerber was entering the market because it had, "identified significant changes in usage that convinced us the timing was right...."

"First," he said, "there is a rapid decline in breast-feeding after mothers leave the hospital." And, "... parent decision regarding baby formula brand selection has grown...."

The irony is inescapable and appalling. In other words, because breastfeeding is declining, more infant formulas should be promoted to the mother. In other words, because some mothers are making feeding decisions on their own, even more mothers should follow suit.

When Nestlé/Carnation entered the marketplace and, again, when Mead Johnson/Bristol-Myers joined with Gerber, we reexamined the Ross philosophy of promoting SIMILAC® Infant Formulas. The result of our deliberations was an even deeper resolve to support the doctor/patient relationship.

Our philosophy remains unchanged. Ross Laboratories has no plans to resort to direct consumer advertising for SIMILAC and our other infant formula products.

We will continue as an ally of health care professionals by supporting your prerogative to prescribe and recommend products as training and experience dictate.

We stand behind you.

Richard W. Gast

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

NEW MANUSCRIPT PROCEDURE

On January 1, 1988, *AJDC* initiated a new procedure. Manuscripts submitted to *AJDC* will NO LONGER BE RETURNED, except in the case of accepted manuscripts or those undergoing author revision. Original artwork and photographs will be returned.

General Information.—Please send manuscripts and correspondence by first-class mail (do not use registered, certified, or express mail) to the Editor, Vincent A. Fulginiti, MD, *AJDC*, Dean's Office, Room 1529, Tulane University, School of Medicine, 1430 Tulane Avenue, New Orleans, LA 70112. All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Reprints are shipped six to eight weeks after publication. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Conforming with all of the steps listed below will facilitate the editorial processing of your manuscript.

Step 1.—Cover Letter.—All manuscripts must be accompanied on submission by a cover letter giving the name, address, affiliation, and telephone number of the corresponding author. The letter must include ALL of the following statements SIGNED BY ALL AUTHORS (ORIGINAL SIGNATURES):

1. **Copyright Release.**—"In consideration of the American Medical Association's taking action in reviewing and editing this submission, the author(s) undersigned hereby transfer(s), assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that this work is published by the AMA."

2. **Statement of Affirmation.**—"This manuscript has not been published anywhere in any language and is not under simultaneous consideration by another publication. This manuscript is original and ALL authors have seen and approve of its contents."

3. **Financial Disclosure.**—List all affiliations with or financial involvement in organizations or entities with a direct financial interest in the subject matter or material of the research discussed in the manuscript (eg, employment consultancies, stock ownership) OR include a statement disclaiming any such involvement. All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosures appropriate for publication. All accepted manuscripts become the permanent property of the publisher (AMA) and may not be published elsewhere without written permission from the AMA. After publication certain articles may appear in translation in the foreign-language edition(s) of *AJDC*.

Step 2.—Manuscript Format.—All articles submitted should have the following features:

1. Four copies of the manuscript should be submitted; three are for transmission to referees and one is to be retained in the editorial office. We prefer an original and three copies.

2. Manuscripts should be typed in triple-spaced format on heavy-duty white bond paper, 21.6 × 27.9 cm (8½ × 11 in) with 2.5-cm (1-in) margins. Do not use justified right margins.

3. Title should be no more than 75 characters.

4. Authors should be limited to six, all of whom have contributed to the study and manuscript preparation, are familiar with its substance, and are able to defend its conclusions.

5. The title page should give full names, degrees, and academic affiliations of all authors, address for request of reprints, and, if the manuscript was presented at a meeting, the organization, place, and exact date on which it was read.

6. Writing style should conform to proper English usage and syntax; consult the *American Medical Association Manual of Style*, available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202.

7. Abstract should be limited to 135 words or less.

8. Each table should be typed, with a title, on a separate sheet of paper, with each line, including headings, double-spaced. Continuations should be on a second sheet with all headings repeated.

9. Use Système International (SI) measurements throughout the manuscript.

10. Illustrations should be high-contrast, glossy prints, in quadruplicate, unmounted and untrimmed; lettering should be legible after reduction to column size. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed on the back of each illustration. Do not write directly on the print.

Magnification and stain should be provided for histologic sections. Full-color illustrations should be submitted as 35-mm, positive color transpar-

mounted transparencies or color prints. Fee is \$400 for up to six square-finished color illustrations that fit on one page. A letter of intent to pay the fee must accompany submission.

All photographs in which there is a possibility of patient identification should be accompanied by a signed statement of consent from both parents (or guardians). Covering eyes to mask identity is not sufficient.

11. References should be listed in order of their appearance in the text, type double-spaced, and in AMA format. Please follow the exact order of information and punctuation in the examples below.

Journal Articles: Sell EJ, Gaines JA, Gluckman C, Williams E. Persistent fetal circulation: neurodevelopment outcome. *AJDC*. 1985;139:25-28.

Books: Krmpotic-Nemanic J, Kostovics I, Rudan P. Aging changes of the form and infrastructure of the external nose and its importance in rhinoplasty. In: Conly J, Dickinson JT, eds. *Plastic and Reconstructive Surgery of the Face and Neck*. New York, NY: Grune & Stratton; 1972:84-91.

Unpublished data, personal communications, or manuscripts "in preparation" or "submitted" should not be included in the list of references. Such material, if essential, may be incorporated in the body of the article.

Authors are responsible for the accuracy of the references.

12. Investigations involving human subjects require a specific statement in the "Methods" section that an appropriate institutional review board approved the project and/or that informed consent was obtained from both legal guardians and/or child, if appropriate.

13. Illustrations and tables from other publications should be suitably acknowledged, with written permission from publisher and author. Brief acknowledgements to specific contributors directly involved in the content of the manuscript may be placed at the end of the text, before the references. General acknowledgements will be deleted.

Step 3.—Special Departments.—Criteria for several special departments are given below.

1. **The Pediatric Forum.**—This is the place for comment, criticism, observations, and discussion of "issues of current concern and importance for children's health," in addition to letters that comment on articles in previous issues of *AJDC*. The Editor reserves the right to conduct review of and to edit all submissions. THE READER SHOULD SUBMIT TRIPLE-SPACED COPY CLEARLY MARKED "FOR PUBLICATION" AND SIGNED BY ALL AUTHORS. REFERENCES, IF INCLUDED, SHOULD CONFORM TO THE USUAL AMA FORMAT. Copyright assignment, signed by all authors, must accompany the original submission.

2. **From Research to Relevance.**—PURPOSE: To focus on significant research that has a high probability of being translated into clinical usefulness.

3. **Educational Interventions.**—PURPOSE: To share information concerning any educational efforts in the broad field of pediatrics.

4. **Sports Medicine.**—PURPOSE: To provide current information related to the medical needs of young athletes, as pertinent to counseling young athletes and their parents regarding sports participation and practices contributing to the health maintenance of the athlete, as well as current concepts in the prevention, diagnosis, and treatment of sports-related illnesses and injuries.

This department of AJDC is reserved for comment, criticism, observation, and discussion of "issues of current concern and importance for children's health." The Editor encourages our readers to express themselves on a variety of topics and issues. Further, we encourage the submission of unique and brief clinical and scientific observations that do not fulfill the criteria for original articles.

Twice-Daily Therapy for Strep?

Sir.—I read with interest the article by Gerber et al¹ in the February 1989 issue of *AJDC*. I was especially interested in his final paragraph. In his conclusion he states that his findings support other recommendations, specifically those of the American Heart Association (AHA), that oral penicillin V potassium can be given in two or three divided doses for 10 days for the treatment of group A streptococcal pharyngitis. I referred to the article cited and found that in fact they do not list twice-daily therapy as an acceptable treatment to prevent rheumatic heart disease.²

For those of us in private practice, it would certainly help to have this issue clarified. Does the AHA approve of twice-daily therapy with penicillin V, or any medication other than a salt of erythromycin, as adequate treatment for group A streptococcal pharyngitis?

In Reply.—In the conclusion of our article,¹ we attempted to make a distinction between our recommendations and those of the AHA. As Dr Gill has correctly observed, the AHA does not list twice-daily penicillin therapy as an acceptable regimen for the treatment of streptococcal pharyngitis.² However, based on our findings³ and those of several other investigators,⁴⁻⁶ we believe that twice-

daily penicillin V therapy is an effective regimen. The Committee on Infectious Diseases of the American Academy of Pediatrics also notes that "with good compliance, two doses of oral penicillin totaling 800,000 U (500 mg) daily have been reported to be effective."⁹

Falls From Pickup Trucks During Childhood

Sir.—Infants and children who are ejected or who fall out of the rear beds

of pickup trucks present a significant but underreported health care issue. Most legislation dealing with child restraint or seat belts issues do not adequately address this problem. We present two cases of children ejected from the rear bed of a pickup truck.

Patient Reports.—PATIENT 1.—A 6-year-old right-handed Navajo boy fell from the back of a pickup truck that was traveling approximately 25 mph over a bumpy rural road. The child struck the frontal portion of his head and experienced a loss of consciousness for a few minutes. After initial evaluation and stabilization, he was transported to our institution. His vital signs on arrival included a heart rate of 70 beats per minute, a blood pressure of 120/65 mm Hg, and a respiratory rate of 20 breaths per minute. Neurologically, he had a Glasgow Coma Score of 9, disconjugate Doll's eyes, right-sided sixth-nerve palsy, and generalized hyperreflexia.

Computed tomography of the brain revealed a small subdural hematoma in the right frontoparietal region with effacement of the right lateral ventricle and a nondepressed right frontal fracture. The patient sustained multiple abrasions. He did not require intracranial pressure monitoring or surgical removal of the subdural hematoma. His condition improved, and he was discharged after 5 days in the hospital with a mild sixth-nerve palsy.

PATIENT 2.—The second patient was a 2-year-old Navajo girl who fell from the back of a slow-moving pickup truck traveling over a rural road. She was initially evaluated and stabilized at another institution, and was noted to have a 7-mm left temporal laceration. Initially, she was crying, combative, and moved all of her extremities. She then became lethargic and unresponsive, and was noted to have jerking eye movements to the right, twitching of her upper extremities, and decreased respirations. The child was endotracheally intubated, given intravenous phenytoin sodium and phenobarbital sodium, and transported to our institution.

On arrival, she was able to withdraw all extremities and open her eyes spontaneously. Computed tomography of her brain revealed a cephalohematoma. It was believed that she had a posttraumatic seizure with secondary respiratory compromise.

he was extubated the next day and had a neurological examination with grossly normal results. She was transferred back to the referring hospital on the second day following the accident.

Comment.—These two patients illustrate the larger number of children treated at our institution with injuries secondary to this mechanism. There is irrefutable evidence that unrestrained children involved in motor vehicle accidents experience higher morbidity and mortality rates than restrained children.^{1,2} This group of children represents the extreme of unrestrained passengers.

Patients 1 and 2 had modified Injury Severity Scores of 18 and 9, respectively. While scores of less than 25 are generally indicative of survival with minimal disability, newer evidence contradicts this. Proportionally more children with head injuries tend to have diffuse rather than focal brain lesions. Children with both "mild" focal and especially diffuse brain injuries often suffer from long-term neuropsychological sequelae.³

Children can be frequently seen riding in the back of pickup trucks where they can easily be ejected during rapid deceleration, fall out during "horseplay" or decreased vigilance, or be injured by road debris. The public and our legislators must be educated. Pediatricians can make this a part of their child restraint and safety education efforts.

Acute Suppurative Adenoiditis

Sir.—A case of isolated adenoiditis prompted a search of the literature for the condition. The results of the search were startling due to the virtual absence of characterization of what

should be a distinctive, and not unusual, clinical entity.

Patient Report.—A previously healthy 9-year-old girl presented with fever, rhinorrhea, pharyngeal pain, and hyponasal speech of 2 days' duration. She reportedly had had a tonsillectomy and adenoidectomy 3 years earlier for recurrent adenotonsillitis. Abnormalities on physical examination were limited to fever (temperature, 40°C), serous rhinorrhea that prompted nearly constant sniffing, total occlusion of the posterior nasal airway, and an exudative fullness just visible in the superior pharynx behind the uvula. Mild posterior cervical adenopathy was also present. A lateral soft-tissue roentgenogram of the head and neck was obtained (Figure). The posterosuperior location and contour of the nasopharyngeal mass seen on the roentgenogram suggested adenoid hypertrophy. Flexible fiberoptic nasopharyngoscopy revealed exudative hypertrophic adenoid tissue filling the nasopharynx and extending into the oropharynx. The patient was treated with penicillin G sodium and showed prompt defervescence with improvement of her nasal obstructive symptoms. Two months later she underwent a thorough secondary adenoidectomy for persistent nasal obstruction. Histologic analysis of the adenoid tissue revealed reactive follicular hyperplasia.

Comment.—Acute suppurative adenoiditis commonly occurs in association with acute tonsillitis.¹⁻⁴ However, adenoiditis existing independently of tonsillitis has only rarely been mentioned in the literature.^{3,5} Isolated adenoiditis occurs either in the presence of normal-appearing tonsils or as in this case when the tonsils have been previously removed. Adenoiditis and obstructive adenoid hypertrophy do not occur following an adenoidectomy unless the adenoid tissue has been incompletely excised.

A nasopharyngeal mass in the setting of an acute illness with fever and nasal obstruction suggests acute suppurative adenoiditis. The differential diagnosis of other nasopharyngeal masses includes nasopharyngeal angiofibroma (usually male patients), Thornwaldt's cyst, teratoma, antrochoanal polyp, nasopharyngeal carcinoma, malignant lymphoma, and rhabdomyosarcoma.

The bacterial pathogens are not well established in isolated cases of adenoiditis due to the infrequent recognition and reporting of this condition. Initial therapy with antibiotics appropriate for the known pathogens of combined adenotonsillitis can be expected to relieve the symptoms of isolated adenoiditis. These organisms include group A β -hemolytic strepto-

Lateral soft tissue of the neck revealing soft-tissue mass filling the nasopharynx.

cocci, other streptococci, *Haemophilus influenzae*, *Branhamella catarrhalis*, *Corynebacterium* species, and various anaerobic organisms.⁴ Persistent evidence of nasal obstruction after the resolution of acute symptoms indicates the need to consider a trial of antibiotic therapy with action against organisms producing β -lactamase or adenoidectomy. Flexible fiberoptic nasopharyngoscopy is useful for initial evaluation and follow-up.

We encourage reports of similar cases to characterize the clinical spectrum of this disease.

Collagenous Colitis in a Child

Sir.—To my knowledge, this instance of collagenous colitis in a 7-year-old boy is the first to be documented in a child. This condition is of unknown etiology and, in this case, appeared to respond to

Stained sections from a rectal biopsy specimen showing the normal surface epithelium, the deposition of collagen as a band beneath the basement membrane, and the sparse chronic inflammatory infiltrate within the lamina propria (hematoxylin-eosin, original magnification $\times 140$ [left] and $\times 320$ [right]).

sulfasalazine therapy. Since the original description by Lindstrom¹ in 1976 of the clinicopathologic syndrome that was labeled *collagenous colitis*, about 50 patients^{2,3} with this condition have been described, all adults.

Patient Report.—A 7-year-old boy had complained of large-volume watery diarrhea for several months; there were up to 10 bowel movements per day. Fasting and/or milk abstinence failed to improve the diarrhea. The feces contained no mucus or blood, and no parasites, ova, or pathogenic bacteria were isolated. Results of fecal occult blood studies were negative, and there was no steatorrhea on fecal fat measurements over a 3-day period. Fecal microscopy showed no undigested food. Results of tests for mucoviscidiosis were negative.

Sigmoidoscopy showed a slightly congested mucosa with no ulceration. On barium follow-through and enema studies some colonic dilatation was identified, but no other abnormality was demonstrable. Serum electrolyte levels and hematologic indexes were also within normal limits; no eosinophilia was present. The erythrocyte sedimentation rate was 30 mm within the first hour.

The rectal biopsy specimen showed no ulceration or active inflammation. The mucosa was of normal thickness with a well-maintained glandular architecture and no edema. A continuous, thick, eosinophilic band of collagenous fibrous tissue between 20 and 25 μm wide was readily identifiable between the surface epithelial lining and the lamina propria. This was stainable with both trich-

rome (for type I collagen [Figure, left]) and reticulin silver (for type III collagen [Figure, right]). Staining for amyloid was negative. The glandular tissue was not atrophic, and the goblet-cell content of the crypts was normal. There was a slight lymphoplasmacytic infiltrate within the lamina propria, but no excess of intraepithelial lymphocytes was seen. No cryptitis was seen in numerous serial sections, and there was no vasculopathy.

The child was treated with sulfasalazine, and over a period of a few months he showed some symptomatic improvement. He did not undergo a repeated biopsy.

Comment.—Collagenous colitis is a histologic diagnosis made in patients with chronic abdominal pain and watery diarrhea in the absence of small-intestinal malabsorption and inflammatory bowel diseases. The findings on proctoscopy and sigmoidoscopy are usually minimal and entirely nonspecific, with no impressive finding that could account for the diarrheal illness. These patients may have up to 20 bowel movements per day, and a large fecal volume of up to 4 L/d may be present. Some loss of weight usually accompanies the condition.

Initial presentation is more often in the sixth or seventh decade of life, but some cases have also been described in patients in their 20s. It affects women with greater frequency.

Collagenous colitis is only diagnosable on microscopy.^{2,3} The histologic

hallmark is the presence in the colon of a subepithelial condensation measuring 10 to 60 μm , composed of collagen fibers, including both type I and type III collagens and fibronectin; this layer appears to be more pronounced on the right side of the colon, and the rectosigmoid mucosa may only show minimal changes.^{3,4} A sparse infiltrate composed of plasma cells, eosinophils, and mast cells may be seen within the lamina propria, but no active inflammatory changes are seen either on the surface or in the crypts, and there are no alterations in goblet cell counts. The width of the collagen band does not appear to correlate with the severity of symptoms and waxes and wanes in its thickness over the years. This collagenous tissue may be reabsorbed completely, and such cases are accompanied by spontaneous regression; anti-inflammatory therapy, such as with local corticosteroids and sulfasalazine, may be similarly effective in removing the collagen.^{5,6}

The hypothesis for the cause of collagenous colitis is that long-standing, focal, superficial damage to the large bowel mucosa results in secondary local repair with scarring.^{4,7} Indeed, there appears to be a spectrum of abnormalities, ranging from "microscopic colitis" with active inflammation to collagenous colitis with fibrosis.³ Local prostaglandin excess has been proposed as the immediate pathogenetic mediator; jejunal aspirates and feces from patients have elevated levels of prostaglandin E_2 .⁸ The "pericrypt fibroblast sheath" was proposed as the end organ for the action of such prostaglandin excess.⁹

Histologic examination of bowel mucosal specimens taken at colonoscopy shows that the condition is not limited to the rectum but may extend as far as the cecum and is indeed often more pronounced in the right side of the colon. There is no known association with any specific drug treatment or with connective-tissue disease, and no excess of circulating intestinal polypeptides or amines has been demonstrated in these patients. In six patients, nonspecific anomalies of connective tissue were present, and these were associated with inflammatory arthropathies.^{3,10} Autoimmune mechanisms have been implicated because of the well-established female prevalence and the anecdotal association with atrophic gastritis, thyroid disease, chronic hepatitis, and primary biliary cirrhosis. No immunoglobulins, complement, or immune complexes have been identified in relation to the collagen band.^{6,8}

Subepithelial deposition of collagen is known to occur also in the small bowel in the condition variously termed *refractory sprue* or *collagenous enteritis*,^{11,12} and, indeed, the nomenclature for this disorder was derived from the small-intestinal counterpart. Antigenic hypersensitivity to dietary proteins other than gluten has been suggested as a cause for small-bowel mucosal fibrosis: milk and soya proteins in infants; and maize, egg, and chicken in adults¹² have been implicated. No such dietary association has been shown in collagenous colitis.

Computed Tomography in the Diagnosis of Osteoid Osteoma in Infancy

Sir.—Osteoid osteoma is a benign bone tumor that principally affects men in

the second decade of life. The clinical manifestations include a characteristic pain with nocturnal exacerbations that recedes or disappears after taking aspirin. In addition, muscular atrophy in the affected extremity and functional impairment are noted. If the tumor is located in the vertebrae, scoliosis can result. The most frequent locations are the femur, tibia, vertebrae, and humerus. A preliminary diagnosis can be made clinically, but confirmation is made by the visualization of the pathognomonic bone lesion, which is the "nidus" surrounded by an area of sclerosis. After surgical treatment, pathological study can confirm the diagnosis by examination of biopsy specimens.

We present a series of patients with osteoid osteoma in whom computed tomography assisted in diagnosis of the lesions.

Patient Reports.—Six children ranging in age from 3 years 5 months to 12 years 6 months were studied and included four boys and two girls with diverse localizations of osteoid osteoma. The clinical symptoms were manifested for a mean of 11 months and consisted of pain with nocturnal paroxysms that improved after administration of aspirin. One patient with osteoid osteoma in the spinal column had scoliosis. In those in whom the osteoma was located in the extremities, muscular atrophy and functional impairment were also observed. The roentgenographic study only identified the specific bone lesion in half of the patients, a characteristic nidus, as well as the perilesional sclerotic bone reaction. All of the patients were treated surgically. The postoperative course was satisfactory for all patients, and the diagnosis of osteoid osteoma was confirmed by pathologic examination.

Comment.—Although the diagnosis of osteoid osteoma can be suspected by the clinical signs and symptoms, it is not unusual that it takes months or years to confirm. The fact that the pain is exacerbated at night and improved with aspirin administration is suggestive of the diagnosis but not specific enough. Due to its rarity in children, it is frequent that the pediatrician does not think of this lesion, above all because the general state of the patient is good and fever or local inflammation is not usually present.¹

The traditional diagnostic test is roentgenography of the affected bone. In the majority of cases, a radiotransparent lesion less than 2 cm in diameter is seen. Its form is oval or round, surrounded by a zone of bone condensation due to reactional hyperostosis.

In other patients, as with our series, a nidus is not visible; therefore computed tomography (CT) of the affected area is indicated.^{2,3} In all of our patients in whom CT was performed, it was possible to identify the nidus and measure its size, which permits differential diagnosis from osteoblastoma. On the other hand, CT also allows the visualization of bone condensation surrounding the nidus, as well as the local muscular atrophy produced by inactivity.

From our results, we conclude that CT is the preferential technique for the diagnosis of osteoid osteomas.

Clear Heads and Bayesian Tales: Predictive Value and the Coin Toss?

Sir.—Drs Halperin and Doyle, in their response to a recent letter,¹ made an assertion that deserves clarification. They stated that "... diagnosing ITP [idiopathic thrombocytopenic purpura] on the basis of a positive serologic test would be as accurate as flipping a coin," given a positive predictive value of approximately 50%. The statement is accurate in this context, since they were referring to data gathered on a population of patients' sera that had a prevalence of ITP of approximately 50%.² In general, however, using a coin flip as a screening test does not produce a fixed positive predictive value of 50%. Instead, it produces a positive predictive value

equal to the *prevalence* of the disease in the population tested.

The distinction is important. If we choose a disease, for example, with a 5% prevalence, then a coin flip will give a positive predictive value of 5%. If, however, another screening test for that disease is found to have a positive predictive value of 50% in that same population, then the screening test is considerably better than a coin flip.

In this example, a patient with a positive test result has a 10 times greater chance of having the disease in question than does a patient with a positive coin flip. Given a disease that is serious and uncommon, and an intervention that is safe, effective, and inexpensive, we might rationally choose to use such a hypothetical test, despite a "rather low positive predictive value."

The point is this: don't automatically disparage a test with a positive predictive value of 50%. When the disease has a low prevalence, such a test is considerably better than a coin flip.

ROBERT D. MAURO, MD
The Children's Hospital
University of Colorado
School of Medicine
Denver, CO 80218

1. Halperin DS, Doyle JJ. High-dose intravenous methylprednisolone for childhood idiopathic thrombocytopenic purpura. *AJDC*. 1988;142:1273-1274.

2. von dem Borne AEGK, van der Lelie H, Vos JJE, et al. Antibodies against cryptantigens of platelets. *Curr Stud Hematol Blood Transfus*. 1986;52:33-46.

In Reply.—Dr Mauro's remarks would be very pertinent if we had suggested in our reply that platelet antibodies should be detected as part of a screening program of ITP in the *general population*. This is not so, however. Such a screening test would be unjustifiable, not only because of its immense costs, but mainly because it would offer no therapeutic or preventive advantage to the patients detected in this manner, as compared with those whose thrombocytopenia has been discovered, as is usually the case, on clinical grounds.

Thus, the controversy regarding the utility of platelet antibody testing is limited to the population of patients with thrombocytopenia and cannot be extrapolated to the general population.

In this setting, our statement on "coin flipping" remains correct. Platelet antibody testing has a positive predictive value for ITP of 50%. In

other words, the probability for a patient with thrombocytopenia of having ITP if the test is positive is only one in two. This is as accurate as flipping a coin.

DANIEL S. HALPERIN, MD
Unité d'onco-hématologie
pédiatrique
Hôpital cantonal universitaire
1211 Geneve 4
Switzerland

In Reply.—Dr Mauro has pointed out a very interesting aspect of the algebra of calculating positive predictive values or PV+.

PV+ is the probability that this subject has the disease tested for (D+) given that the test for the disease is positive (T+). PV+ can be written as $\text{prob}(D+/T+) = \text{the probability of the disease given a positive test}$.

This is a classic Bayes' formula issue and a subtle one that I have not seen discussed anywhere in my reading. For the record, I will go through the algebra in case someone challenges Dr Mauro's assertions.

$$PV+ = \frac{\text{Prev} \times \text{pr}(T+/D+)}{[\text{Prev} \times \text{pr}(T+/D+)] + [(1 - \text{Prev}) \times \text{pr}(T+/D-)]}$$

If you flip a coin instead of performing a test, you will get $\text{pr}(T+/D+) = 0.50$; that is, the probability of a positive test T+ is the probability of, say, "heads."

Also, the probability of a positive test among subjects without the disease, $\text{pr}(T+/D-)$, will also be .50.

Putting these probabilities into the equation, we get the following:

$$PV+ = \frac{\text{Prev} \times .50}{[\text{Prev} \times .50] + [(1 - \text{Prev}) \times .50]}$$

The .50s cancel out, leaving the following:

$$PV+ = \frac{\text{Prev}}{(\text{Prev}) + (1 - \text{Prev})} = \frac{\text{Prev}}{1} = \text{Prevalence}$$

This may seem needlessly esoteric, but to readers who do not think often about Bayes, PV+, or prevalence, the letter may not be intuitively obvious.

An added benefit of the letter is that it reminds us all that PV+ (the predictive value of any test) is always related to the prevalence of the disorder in the population being subjected to the test. This is why a test that performs very well in a clinic that has a high prevalence of a disease may perform poorly as a screening test in

a population with low prevalence of the disease.

For those who view these matters in a less algebraic way, the situation could be looked at differently. The test users apply a test to a population that presents itself to the clinic, hospital, or bootcamp where the test is employed. The disease of interest occurs in the population in some prevalence (PREV).

A coin flip is one way to select half of any group of subjects from the presenting population. If one were to view a flip of "heads" as a "positive test for D" this would result in half of the subjects being called positive for D. What proportion of these would actually have the disease? The same proportion as in the source population, because the coin flip has simply selected a random half of the subjects who are tested.

The proportion of subjects with D in the source population is called the PREV. The proportion with D in the "positives" will be the same (ie, equal to PREV).

In the half who got "tails" and were judged to be "negative" for D, the proportion with the disease would also be the same as in the source (ie, the PREV). This means that the proportion of false negatives also equals the PREV.

Even more general, if one selects any subset of subjects from the source population by any kind of random device (eg, a table of random numbers), that subset will have D in nearly the same proportion as the source population, PREV. The random device will yield PV+ that is equal to the PREV.

Priapism Following Testosterone Therapy for Delayed Puberty

Sir.—The article by Kaplowitz¹ in the January 1989 issue of *AJDC* again underscores the usefulness of testosterone as an agent for the diagnosis and treatment of delayed puberty. The safety of this therapy is implied in this and other articles discussing this treatment modality.¹⁻³ There is a statement in Kaplowitz's article, similar to that in other articles written on this subject: "Although more frequent erections were noted, this was not felt

to be excessive in any patient." While such a statement appears true for the majority, it is important to note that prolonged painful erections do occur on occasion during such testosterone therapy. We have recently observed three patients who developed prolonged erections during testosterone therapy, one resulting in clinical priapism.

Patient Reports.—PATIENT 1.—A 14-year-7-month-old boy with Tanner stage I sexual development and a growth rate of 3.2 cm/y during the 18 months prior to testosterone therapy received a single 200-mg injection of testosterone enanthate, as the first of four injections. Five days after injection, the patient developed a prolonged nocturnal erection that continued for 5 to 6 hours while at school. Because of embarrassment, he did not tell anyone about his prolonged painful erection until that afternoon when his parents returned home. He was taken to the emergency department at least 8 hours after the inception of his erection and did not respond to amyl nitrite therapy. Our pediatric urologist diagnosed clinical priapism and recommended percutaneous penile irrigation with heparinized saline to remove clotted blood. The patient responded well to the irrigation, but 1 year later, despite entering puberty, he reported no subsequent erections. Clotting studies revealed no abnormalities. A history of some manipulation of the erected penis was elicited as the only

"risk factor" for prolonged erection.

PATIENT 2.—A 14-year-5-month-old boy was treated with testosterone enanthate, 100 mg intramuscularly, as the first of four doses. Following the initial dose, the patient developed a prolonged erection lasting 3 hours. As the patient had been warned to seek medical attention if he had an erection for more than 1 hour, he was taken to the emergency department where he responded to amyl nitrite therapy. The patient had no problems with the next three testosterone doses and has had the expected pubertal response.

PATIENT 3.—A 13-year-9-month-old boy was treated with testosterone enanthate, 100 mg intramuscularly, as the first of four doses. Following this initial injection, he developed a prolonged erection lasting for greater than 1 hour. The patient had been warned to seek medical attention for prolonged erections and thus was seen in the emergency department 2 hours after onset of the prolonged erection. He responded to amyl nitrite therapy. He had no problems with the next three doses and has had the expected pubertal response.

Comment.—Certainly, clinical priapism associated with testosterone therapy is an unusual complication of testosterone therapy for delayed puberty. One isolated case of priapism developing after testosterone injection does not establish a causal connection. Our patient 1 may have had idiopathic priapism, accentuated by the testosterone administration and/

or manual stimulation. However, our experience underscores the need to alert patients and their parents that prolonged erections may occur during testosterone therapy, especially following the initial injection. Prompt evaluation and management of such erections is imperative. The erections generally abate following a cold shower or after inhaling amyl nitrite; however, left untreated, they may result in clinical priapism.

NEW

For the symptoms of allergic rhinitis...

DESIGNED TO DELIVER

Now NASALCROM is available in the ready-to-use pump spray your patients have been asking for! The new NASALMATIC® fully-assembled unit comes in two convenient sizes: For your chronic allergic rhinitis patients, the new 26 mL size is a handy, economical alternative to the purchase of frequent refills. For your patients with seasonal symptoms, the regular 13 mL size is ideal.

Inside the new NASALCROM unit is the proven formula patients rely on for relief of sneezing, itching, runny nose, and congestion.^{1,2} NASALCROM provides protection from the first dose¹ and symptom relief within days.² And it works without the annoying side effects typical of other first-line allergic rhinitis medications.^{3,4}

Nonsedating NASAL SOLUTION, 40 mg/mL
NASALCROM®
(cromolyn sodium/FISONS)

**IN THE NEW FULLY-ASSEMBLED UNITS
(26 mL AND 13 mL)**

Please see adjacent page for Brief Summary of Full Prescribing Information.

NASAL SOLUTION, 40 mg/mL

NASALCROM[®]

(cromolyn sodium nasal solution, USP)

Brief Summary

DESCRIPTION: Each milliliter of NASALCROM[®] Nasal Solution (cromolyn sodium nasal solution, USP) contains 40 mg cromolyn sodium in purified water with 0.01% benzalkonium chloride to preserve and 0.01% EDTA (edetate disodium) to stabilize the solution.

INDICATIONS: NASALCROM is indicated for the prevention and treatment of the symptoms of allergic rhinitis.

CONTRAINDICATIONS: NASALCROM is contraindicated in those patients who have shown hypersensitivity to any of the ingredients.

PRECAUTIONS: General: Some patients may experience transient nasal stinging and/or sneezing immediately following instillation of NASALCROM. Except in rare occurrences, these experiences have not caused discontinuation of therapy. In view of the biliary and renal routes of excretion for cromolyn sodium, consideration should be given to decreasing the dosage or discontinuing the administration of the drug in patients with impaired renal or hepatic function.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Long term studies in mice (12 months intraperitoneal treatment followed by 6 months observation), hamsters (12 months intraperitoneal treatment followed by 12 months observation), and rats (18 months subcutaneous treatment) showed no neoplastic effect of cromolyn sodium.

No evidence of chromosomal damage or cytotoxicity was obtained in various mutagenesis studies.

No evidence of impaired fertility was shown in laboratory animal reproduction studies.

Pregnancy: Pregnancy Category B. Reproduction studies with cromolyn sodium administered parenterally to pregnant mice, rats, and rabbits in doses up to 338 times the human clinical doses produced no evidence of fetal malformations. Adverse fetal effects (increased resorptions and decreased fetal weight) were noted only at the very high parenteral doses that produced maternal toxicity. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Drug Interaction During Pregnancy: Cromolyn sodium and isoproterenol were studied following subcutaneous injections in pregnant mice. Cromolyn sodium alone in doses of 60 to 540 mg/kg (38 to 338 times the human dose) did not cause significant increases in resorptions or major malformations. Isoproterenol alone at a dose of 2.7 mg/kg (90 times the human dose) increased both resorptions and malformations. The addition of cromolyn sodium (338 times the human dose) to isoproterenol (90 times the human dose) appears to have increased the incidence of both resorptions and malformations.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when NASALCROM is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established.

ADVERSE REACTIONS: The most frequent adverse reactions occurring in the 430 patients included in the clinical trials with NASALCROM were sneezing (1 in 10 patients), nasal stinging (1 in 20), nasal burning (1 in 25), and nasal irritation (1 in 40). Headaches and bad taste were reported in about 1 in 50 patients. Epistaxis, postnasal drip, and rash were reported in less than one percent of the patients. One patient in the clinical trials developed anaphylaxis.

Adverse reactions which have occurred in the use of other cromolyn sodium formulations for inhalation include angioedema, joint pain and swelling, urticaria, cough, and wheezing. Other reactions reported rarely are serum sickness, periarteritic vasculitis, polymyositis, pericarditis, photodermatitis, exfoliative dermatitis, peripheral neuritis, and nephrosis.

CAUTION: Federal law prohibits dispensing without prescription.

OVER A CENTURY AGO, a thousand visionary physicians across the nation bestowed a commemorative stone carving to the Washington Monument. This patriotic display symbolized their unrelenting devotion to a new republic founded on freedoms—including the freedom to practice medicine for the best possible health of all its people. *Today your help is needed to restore this symbol of our profession.*

Because the commemorative stone has suffered from severe erosion and defacement, the American Medical Association is launching a campaign to raise money from physicians to restore this symbol of medicine for the National Park Service. Every contribution made to this effort will serve as a statement of each physician's personal affirmation and commitment to health and medicine in America.

Please take part in rededicating the commemorative stone as a shining example of the strength of medicine in a free and strong society. Contributors who donate \$100 or more will receive a memorial replica of the carving as a token of appreciation. Send your tax deductible contribution for this timeless symbol today. Thank you.

Yes, I want to affirm my commitment to health and medicine in America.

Please accept my contribution for:

Thank you for your contribution.

Why Wait for DTP-E-IPV?

In January 1988, a prestigious panel appointed by the Institute of Medicine (IOM) reviewed policy options for vaccination against poliomyelitis.¹ The IOM last reviewed this subject in 1977, at which time it concluded that live, trivalent oral poliovirus vaccine (OPV) was the preferred vaccine but recommended killed, inactivated poliovirus vaccine (IPV) for immunodeficient people and those with immunodeficient family contacts.

See also p 1007.

The new IOM review was prompted in part by licensing of an enhanced potency inactivated polio vaccine (E-IPV). This vaccine, produced in human diploid cells, has a higher antigenic content than does conventional IPV and, therefore, children can be satisfactorily immunized with fewer doses.² A combined diphtheria and tetanus toxoids and pertussis vaccine (DTP)-E-IPV will likely become available within 2 to 5 years.

Other developments prompting the IOM review included the following: (1) the probable interruption of transmission of wild polio virus in the United States; (2) the immunization of an increased proportion of US children (95% of those entering school in 1985-1986); (3) a decreased chance of importation of wild polio due to campaigns in other nations to reduce polio; (4) the development of new technology enabling differentiation of wild vs vaccine-related polio; (5) the recognition that the risk of vaccine-related polio varies with each dose of OPV (for the first dose, the risk is 1:560 000); (6) an increasing number of immunocompromised children and adults due to human immunodeficiency virus infection; and (7) continued immunization litigation.

The IOM concluded that:

No change in the present policy is recommended at this time except that E-IPV

should be substituted for IPV . . . After E-IPV combined with diphtheria-tetanus-pertussis is licensed . . . consideration should be given to a regimen of two or more doses of DTP-E-IPV . . . followed by OPV at 18 months and at entry to elementary school.

The IOM saw the central issue as whether the current small risk of vaccine-associated polio can be reduced further without an adverse impact on poliomyelitis control in the United States. The panel noted that "because E-IPV does not spread to contacts, it would need to achieve and maintain higher levels of direct vaccine-induced immunity to pre- and post-school-age populations." Also, because E-IPV does not produce as high a level of intestinal immunity as OPV, it seems likely that wild polio virus, if imported, would spread more widely.

The panel noted that an ethical difference exists between recommending live vs killed polio vaccine or a mixed live/killed schedule. They observed that vaccine-associated paralytic polio occurs principally among the susceptible children and parents who participate in live vaccination programs. This risk is avoided if a killed vaccine is used and diminished if a killed vaccine is given before a live vaccine is used. The IOM panel stated that:

Most parents concerned only for their child's welfare and informed about the nature of the alternatives would be likely to prefer one of the IPV vaccination strategies. With the current OPV vaccination strategy, cooperating parents and children are asked to bear the risk of vaccine-associated paralysis in order to spread the benefit of immunity to others who fail to have themselves or their children vaccinated.

Recognizing the relatively higher risk of paralytic disease following the first dose of OPV, the panel concluded that a vaccination schedule "in which two or more doses of E-IPV were given prior to OPV would reduce or even eliminate cases of vaccine-associated

paralysis in recipients of OPV and in their contacts." Therefore, the panel recommended a combined E-IPV/OPV schedule to reduce the incidence of vaccine-associated polio but maintain a high degree of intestinal immunity in the population to prevent the spread of wild virus. The panel also noted that if E-IPV was not combined with DTP, additional injections and possibly additional visits would be required to complete the immunization schedule.

The panel expressed concern that a mixed program of E-IPV and OPV "is administratively more complicated and more costly" and stated specifically that the mixed E-IPV/OPV program is not recommended if DTP and E-IPV must be given separately. Only after E-IPV combined with DTP is licensed did the panel suggest consideration be given to a regimen of two or more doses of DTP-E-IPV followed by OPV at age 18 months.

The panel observed that more information is needed about the following questions: (1) Is wild polio virus circulating in the United States? (2) What are the levels of immunity among young adults and preschool children? (3) To what extent does OPV vaccine virus spread to contacts of recipients and induce immunity? (4) What would be the optimal combined E-IPV/OPV vaccine strategy? It is precisely because the answers to these questions are not known that practitioners look to panels of experts for recommendations.

The IOM panel's rationale for a combined schedule is cogent. Many knowledgeable, thoughtful observers are no longer convinced that the "price" of vaccine-associated polio must be paid to protect this nation against wild polio virus. On the other hand, there are not sufficient data to assure such observers that complete reliance on inactivated vaccine would provide comparable protection against com-

munity spread of wild polio virus following its introduction. Therefore, a combined E-IPV/OPV schedule that should lower the number of vaccine-associated cases (albeit not eliminating all of them) while preserving a high incidence of intestinal immunity seems wise. But why wait?

The potential benefits of such a change in vaccine policy may be marginal when viewed from a nationwide or generational perspective. For the patients, families, or physicians involved in each vaccine-associated case, the potential benefit is far from marginal. Why should introduction of a combined E-IPV/OPV schedule await the production of a combined DTP-E-IPV vaccine? Why shouldn't those who wish to lower their risk of vaccine-associated polio *now* opt for a combined IPV/OPV schedule? The IOM panel's concern is, that because such a schedule is more costly and might prove cumbersome, the total number of children successfully immunized might decrease. The panel viewed this as an inappropriate "cost" given the relatively marginal benefit of a combined schedule for vaccine-associated cases.

A combined OPV and IPV schedule in the absence of a combined DTP-E-IPV vaccine will likely cost more. In January 1989, in Seattle, Wash, E-IPV cost approximately \$14 a dose vs \$9.50 a dose for OPV. Also,

a combined E-IPV/OPV schedule would, at this time, require two or three additional subcutaneous injections. Were such a schedule now recommended *exclusively*, there might well be some decrease in the total number of children protected because the prompt availability of increased funds for immunization could not be assured.

No one wishes to advocate different immunization policies for patients immunized in public clinics vs private offices. But postponing a preferred strategy because of cost raises difficult issues. The price of vaccine is affected by the size of the potential market: the price of E-IPV would almost certainly decrease were its use mandated and vaccine for public immunization programs purchased by federal contract, as is OPV. In the absence of such a mandate, the market will likely remain small and the price high. The additional cost of administering two or three subcutaneous injections of E-IPV vs two or three oral doses of OPV is less easily determined, but it is likely to be the major increased cost that needs to be balanced against the benefit of a reduced risk of paralytic disease among vaccinees and their contacts until a combined DTP-E-IPV is available.

The question answered by the IOM and the one implicitly posed by parents to their children's physicians are

subtly different. The IOM was asked: What is now the optimal vaccination policy for control of polio in the *nation*? The parent asks, What is now the optimal way to protect *my child and family* against polio? What if the practitioner is confident the family will persevere despite the need for two or three more shots and a slightly more expensive schedule to reduce their child's risk of vaccine-associated polio from approximately 1 in 560 000 to 1 in 10.5 million? If, in the judgment of the child's physician and parents, the cost and discomfort of a combined E-IPV and OPV schedule is acceptable, it seems the optimal way to immunize an individual child against polio *today*.

Poliovirus Vaccine Policy

Another Perspective

Throughout the 1950s parents greeted each summer with mounting anxiety as outbreaks of polio were responsible annually for 20 000 to 25 000 cases of paralytic disease. In 1954, the Fran-

See also p 1006.

cis field trial demonstrated the efficacy of inactivated polio virus vaccine (IPV) in the prevention of this dread infection. Beginning in 1955, widespread use of IPV resulted in a marked decline in the annual reported incidence of polio. In

1959, however, there was an incipient upswing in the number of people contracting polio, a significant proportion of whom had previously received three or more injections of IPV. Coupled with the dramatic reports of the success of oral polio virus vaccine (OPV) in Europe and other parts of the world, a shift took place in 1961 in the United States with a transition from the IPV to an OPV program. Soon thereafter, reported cases of paralytic disease due to polioviruses plummeted to levels less than 100 cases per year with the virtual

disappearance of epidemic disease. The last outbreak in our country occurred in 1979 and involved only 10 cases within an Amish population who, for religious reasons, had declined immunization.

Aside from the solitary cases of polio recognized annually as imported from abroad, nearly all the reports now (from two to eight per year) are of OPV vaccine-associated paralytic disease, either in recipients or their contacts.¹ The failure of the imported cases to initiate a cluster of paralytic disease attests to the excellence of our

individual and community immunologic barriers to spread. The focus of the IPV-OPV debate continues to be the diminishing number of vaccine-associated cases (there were two cases in the preliminary report for 1988) as "the price" we pay for national control of polio. Vaccine-associated paralytic disease has been carefully studied, and with modern molecular virologic techniques² it is possible to show that many, if not most, cases result from a mutation of the type III vaccine virus component. A very small proportion of the vaccine-associated cases (<10%) occur among individuals with severe immunodeficiency disorders who are inadvertently fed OPV prior to the diagnosis of their underlying disease. Results of genetic manipulations of the OPV seed strains, especially type III, offer encouragement that a more stable mutant is achievable, ensuring preservation of immunogenicity with loss of potential for reversion to neurovirulence.

Throughout the past several decades, proponents of IPV have pointed to the admirable records of polio elimination in a number of European countries (especially Holland and several of the Scandinavian nations) where IPV alone had been used. In the last 10 years, however, several unsettling events occurred in these nations and elsewhere. In 1978, 110 cases of type I disease occurred in the Netherlands among a population who had refused immunization. In 1984 to 1985, an outbreak of type III paralytic polio in Finland resulted in nine cases of paralytic disease, five of them among individuals who had previously received as many as five doses of IPV. In both outbreaks, there was evidence of widespread dissemination of the "wild" virus by healthy, IPV-immunized schoolchildren. This raised the oft-debated issues of both the individual value of gastrointestinal tract immunity and its barrier as community protection against circulation of virulent virus and outbreaks of paralytic polio. Probably the most cogent example occurred recently in one district (Hadera) of Israel. In 1982, that district chose to discontinue OPV and to adopt the new, enhanced IPV (E-IPV) for its routine immunization schedule.

In the summer and fall of 1988, 12 cases of paralytic disease occurred in Hadera, principally among individuals over 17 years of age. Studies of fecal excretion of schoolchildren revealed widespread dissemination and shedding of the responsible agent, a "wild" type I virus. Although the children themselves were not the victims of paralytic disease, their susceptible gastrointestinal tracts served as the reservoirs and vectors for transmission of the "wild" virus, which was successful in infecting those young adults who had incomplete immunity. In these considerations, it is important to remember that the populations of Finland and Israel total 4.8 and 4.6 million, respectively, so that such numbers extrapolated to a nation of our size could have meant from 450 to 600 cases of paralytic disease.

On two occasions, the Institute of Medicine of the National Academy of Sciences, Washington, DC, has been asked to assemble expert panels to consider polio vaccine immunization policy for the United States. In 1977, such a conference resulted in a recommendation that OPV continue as the primary vaccine for our country and that IPV be available for selected individuals who might be at increased risk for the rare paralytic events of OPV. In 1988, a similar conference was held at the Institute of Medicine and the issues were extensively reexamined. The recommendations were that OPV be maintained as the primary vaccine, but that consideration be given to a combined schedule involving E-IPV to be followed by OPV, once it was possible to combine E-IPV with diphtheria and tetanus toxoids and pertussis (DTP) vaccine. In this way, the childhood immunization schedule could be maintained in its present form with only minor changes that would be unlikely to result in an increased number of child health visits or a diminution of vaccine coverage. Currently, there are vaccines used abroad that combine E-IPV with DTP, but these use the whole-cell pertussis vaccine, which is itself currently under scrutiny in this country and elsewhere. Most vaccine producers are reluctant to move into the mode of combined E-IPV/DTP until a decision

has been made regarding the use of newer acellular pertussis vaccines. The progress of these studies has been reported elsewhere.³

Lengthy debates, both oral and written, have been conducted regarding polio vaccine policies. Recent articles^{4,5} summarize fully the protagonists' views. Dr Marcuse, in a separate editorial in this issue of *AJDC*, suggests that we move ahead now with the E-IPV/OPV combined schedule without the recommendation of the American Academy of Pediatrics or public health groups (such as the Immunization Practices Advisory Committee).

Although Dr Marcuse's suggestion may eventually be similar to recommended policies, there are unanswered questions that expert advisory committees believe should be addressed before any major change is made in our vaccine policy. These relate to the same questions that arose with the outbreaks in Finland and Israel: (1) How important is circulation of the oral vaccine virus in the establishment of immunity among preschoolchildren who do not receive any vaccine? (2) How important is gastrointestinal tract immunity in preventing the circulation of wild polioviruses introduced from nations where endemic disease persists? (More than 1700 cases of suspected paralytic polio were reported in 1988 in Central and South America.⁶) (3) How effective is our health care system in providing immunization for the target population, children under 2 years of age? (Current outbreaks of measles among infants from urban areas who have not been immunized have been studied in Los Angeles, Calif, Houston, Tex, New York, NY, and other areas where such populations are increasing.) Although more than 97% of youngsters entering school have been properly immunized because of entry requirements, the preschool populations in some areas have immunization rates as low as 50%. Until we have established a health care provision system that ensures the immunization of nearly 100% of such youngsters, can we rely on an unfulfilled E-IPV/OPV combined schedule that may leave many such youngsters with neither

humoral nor gastrointestinal tract immunity? Our success in preventing the spread of any of the recent introductions of wild poliovirus in this country has depended on high levels of immunity engendered by the widespread use and circulation of OPV and its establishment of gastrointestinal tract immunity.

Another major concern of a premature adoption in this country of the combined E-IPV/OPV schedule would be the likely establishment of a "two-class" system. Those infants whose care is in private physicians' offices might receive the combined schedule; those in public health clinics would continue with OPV alone. Such a disparity in child health care is contrary

to the spirit of child advocacy embraced by pediatricians. Current estimates reveal that at least 50% of preschool children are immunized in public health clinics. Until the problems of acellular pertussis vaccine have been successfully resolved, until the questions posed by advisory committees regarding the current assets of OPV in the United States have been investigated, and until vaccines can be delivered to all children in the first 2 years of life, a change may be premature.

Alupent® (metaproterenol sulfate)

Tablets	Inhalation Aerosol	Syrup	Inhalation Solution	Inhalation Solution
10 and 20 mg	15 ml†	10 mg/5 ml	5% 10 ml and 30 ml	Unit-dose Vials 0.4% and 0.6%

†15 mg/ml (each metered dose delivers 0.65 mg metaproterenol sulfate)

Brief Summary of Prescribing Information

CONTRAINDICATIONS Use in patients with cardiac arrhythmias associated with tachycardia is contraindicated.

Although rare, immediate hypersensitivity reactions can occur. Therefore Alupent® (metaproterenol sulfate USP) is contraindicated in patients with a history of hypersensitivity to any of its components.

WARNINGS Excessive use of adrenergic aerosols is potentially dangerous. Fatalities have been reported following excessive use of Alupent® (metaproterenol sulfate USP) as with other sympathomimetic inhalation preparations, and the exact cause is unknown. Cardiac arrest was noted in several cases. Paradoxical bronchoconstriction with repeated excessive administration has been reported with sympathomimetic agents. Therefore, it is possible that this phenomenon could occur with Alupent. Patients should be advised to contact their physician in the event that they do not respond to their usual dose of a sympathomimetic amine aerosol.

PRECAUTIONS Because Alupent® (metaproterenol sulfate USP) is a sympathomimetic drug, it should be used with great caution in patients with hypertension, coronary artery disease, congestive heart failure, hyperthyroidism or diabetes, or when there is sensitivity to sympathomimetic amines.

Information for Patients Extreme care must be exercised with respect to the administration of additional sympathomimetic agents. A sufficient interval of time should elapse prior to administration of another sympathomimetic agent.

Carcinogenesis Long-term studies in mice and rats to evaluate the oral carcinogenic potential of metaproterenol sulfate have not been completed. Studies of metaproterenol sulfate have not been conducted to determine mutagenic potential or effect on fertility.

Pregnancy *Teratogenic Effects.* Pregnancy Category C. Alupent has been shown to be teratogenic and embryocidal in rabbits when given orally in doses 620 times the human inhalation dose and 62 times the human oral dose. There are no adequate and well-controlled studies in pregnant women. Alupent should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Oral reproduction studies in mice, rats and rabbits showed no teratogenic or embryocidal effects at 50 mg/kg, corresponding to 310 times the human inhalation dose and 31 times the human oral dose. Teratogenic effects in the rabbit included skeletal abnormalities and hydrocephalus with bone separation.

Nursing Mothers It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Alupent is administered to a nursing woman.

Pediatric Use Consult package insert for age limit.

ADVERSE REACTIONS Adverse reactions are similar to those noted with other sympathomimetic agents. Adverse reactions such as tachycardia, hypertension, palpitations, nervousness, tremor, nausea and vomiting have been reported.

The most frequent adverse reactions to Alupent® (metaproterenol sulfate USP) Inhalation Solution are nervousness and tachycardia which occur in about 1 in 7 patients, tremor which occurs in about 1 in 20 patients and nausea which occurs in about 1 in 50 patients. Less frequent adverse reactions are hypertension, palpitations, vomiting and bad taste which occur in approximately 1 in 300 patients.

HOW SUPPLIED *Inhalation Aerosol:* Each canister of Alupent® (metaproterenol sulfate USP) Inhalation Aerosol contains 225 mg of metaproterenol sulfate as a micronized powder in inert propellants. Alupent Inhalation Aerosol with mouthpiece (15 ml). Alupent Inhalation Aerosol refill (15 ml). Store below 77°F (25°C). Avoid excessive humidity.

Inhalation Solution: Alupent Inhalation Solution is supplied as a 5% solution in bottles of 10 ml or 30 ml with accompanying calibrated dropper.

Store below 77°F (25°C). Protect from light. Do not use the solution if it is brown or has a precipitate. Alupent Inhalation Solution Unit-dose Vial is supplied as a 0.4% or 0.6% clear colorless or nearly colorless solution containing 2.5 ml with 25 vials per box. Store below 77°F (25°C). Protect from light. Do not use the solution if it is brown or has a precipitate.

Syrup: Alupent is available as a cherry-flavored syrup, 10 mg per teaspoonful (5 ml), in 16 fl. oz. bottles. Store below 86°F (30°C). Protect from light.

Tablets: Alupent is supplied in two dosage strengths as scored, round white tablets in bottles of 100. Tablets of 10 mg coded BI/74. Tablets of 20 mg coded BI/72.

Storage for bottles: Store below 86°F (30°C). Protect from light.

Storage for blister samples: Store below 77°F (25°C). Protect from light.

Consult package insert before prescribing.

A safe, more effective method of ear curettage. Both the *Flex-Loop* and the *Infant Ear Scoop* are designed to quickly and

HERE'S THE SCOOP

easily remove cerumen while avoiding trauma to the ear canal. The low cost makes them easily affordable and their single use disposability eliminates the risk of contamination.

The *Flex-Loop* flexible ear curette is made of virtually unbreakable polypropylene, allowing the loop to flex and conform to ear anatomy — particularly valuable in a young child. Yet the *Flex-Loop* is stiff enough to remove most types of cerumen quickly and easily, allowing a clear view for accurate evaluation of the tympanic membrane.

Newly available is the smaller *Infant Ear Scoop*, specially designed for the tiniest of ear canals. Its 2 mm width was created in response to physician demand, with a spoon-like design that provides effective removal of cerumen, and a tear-drop shape that allows safe and comfortable curettage of the infant ear.

Recommendations of the Immunization Practices Advisory Committee (ACIP)

General Recommendations on Immunization

THIS REVISION OF the "General Recommendations on Immunization" updates the 1983 statement.¹ Changes or new sections include 1) listing of vaccines available in the United States by type and recommended routes, 2) updated schedules for immunizing infants and children, 3) clarification of the guidelines for spacing administration of immune globulin preparations and different vaccines, 4) an updated table of recommendations for routine immunization of children infected with human immunodeficiency virus, 5) listing of conditions that are often inappropriately considered contraindications to immunization, and 6) addition of information on the National Childhood Vaccine Injury Act of 1986 and the National Vaccine Injury Compensation Program. These recommendations are not comprehensive for each vaccine; Immunization Practices Advisory Committee (ACIP) recommendations on each vaccine should be consulted for more details.

INTRODUCTION

Recommendations for immunizing infants, children, and adults are based on characteristics of immunobiologics, scientific knowledge about the principles of active and passive immunization, and judgments by public health officials and specialists in clinical and preventive medicine. Benefits and risks are associated with the use of all immunobiologics: no vaccine is completely safe or completely effective. Benefits of immunization range from partial to complete protection against the consequences of disease (which range from mild or asymptomatic infection to severe consequences, such as paralysis or death); risks of immunization range from common, trivial, and inconvenient side effects to rare, severe, and life-threatening conditions. Thus, recommendations for immunization practices balance scientific evidence of benefits, costs, and risks to achieve optimal levels of protection against infectious diseases. These rec-

ommendations describe this balance and attempt to minimize the risks by providing specific advice regarding dose, route, and spacing of immunobiologics and delineating situations that warrant precautions or contraindicate their use. They are recommendations for use in the United States because epidemiologic circumstances and vaccines often differ in other countries. Individual circumstances may warrant deviations from these recommendations. The relative balance of benefits and risks can change as diseases are controlled or eradicated. For example, because smallpox has been eradicated throughout the world, the risk of complications associated with smallpox vaccine now exceeds the risk of the disease; consequently, smallpox vaccination of civilians is now indicated only for laboratory workers directly involved with smallpox or closely related orthopox viruses (e.g., monkeypox and vaccinia).

DEFINITIONS

Immunobiologic

Immunobiologics include both antigenic substances, such as vaccines and toxoids, and antibody-containing preparations, including globulins and antitoxins, from human or animal donors. These products are used for active or passive immunization or therapy. Examples include:

Vaccine: A suspension of live (usually attenuated) or inactivated microorganisms (bacteria, viruses, or rickettsiae) or fractions thereof administered to induce immunity and thereby prevent infectious disease. Some vaccines contain highly defined antigens (e.g., the polysaccharide of *Haemophilus influenzae* type b or the surface antigen of hepatitis B); others have antigens that are complex or incompletely defined (e.g., killed *Bordetella pertussis* or live attenuated viruses).

Toxoid: A modified bacterial toxin that has been rendered nontoxic but retains the ability to stimulate the formation of antitoxin.

Immune globulin (IG): A sterile solution containing antibodies from human blood. It is obtained by cold ethanol fractionation of large pools of blood plasma and contains 15%-18% protein. Intended for intramuscular administration, it is primarily indicated for routine maintenance of immunity of certain immunodeficient persons and for passive immunization against measles and hepatitis A. IG does not transmit hepatitis B virus, human immunodeficiency virus (HIV), or other infectious diseases.

Intravenous immune globulin (IGIV): A product derived from blood plasma from a donor pool similar to the IG pool but prepared so it will be suitable for intravenous use. IGIV does not transmit infectious diseases. It is primarily indicated for replacement therapy in antibody-deficiency disorders.

Specific IG: Special preparations obtained from blood plasma from donor pools preselected for a high antibody content against a specific antigen, e.g., hepatitis B immune globulin (HBIG), varicella-zoster immune globulin, rabies immune globulin, and tetanus immune globulin. Like IG and IGIV, these preparations do not transmit infectious diseases.

Antitoxin: A solution of antibodies derived from the serum of animals immunized with specific antigens (e.g., diphtheria antitoxin, botulinum antitoxin) used to achieve passive immunity or for treatment.

Vaccination and Immunization

These terms are often used interchangeably. Vaccination and vaccine derive from vaccinia, the virus once used as smallpox vaccine. Thus, vaccination originally meant inoculation with vaccinia virus to render a person immune to smallpox. Although some persons still prefer that vaccination be restricted to this use, most use it to denote the administration of any vaccine or toxoid.

Immunization is a more inclusive

term denoting the process of inducing or providing immunity artificially by administering an immunobiologic. Immunization can be active or passive.

Active immunization is the production of antibody or other immune responses to the administration of a vaccine or toxoid. Passive immunization means the provision of temporary immunity by the administration of preformed antibodies. Three types of immunobiologics are administered for passive immunization: 1) pooled human IG or IGIV, 2) specific IG preparations, and 3) antitoxins.

Vaccination and immunization are used interchangeably in ACIP statements in reference to active immunization. Regardless of which term is used, administration of an immunobiologic cannot be automatically equated with the development of adequate immunity for a variety of reasons, many of which are discussed below.

IMMUNOBIOLOGICS

The specific nature and content of immunobiologics can differ. When immunobiologics against the same infectious agents are produced by different manufacturers, active and inert ingredients in the various products are not always the same. Practitioners are urged to become familiar with the constituents of the products they use.

Suspending Fluids

These may be sterile water or saline or complex fluids containing small amounts of protein or other constituents derived from the medium or biologic system in which the vaccine is produced (e.g., serum proteins, egg antigens, cell-culture-derived antigens).

Preservatives, Stabilizers, Antibiotics

These components of vaccines, antitoxins, and globulins are used to inhibit or prevent bacterial growth in viral cultures or the final product or to stabilize the antigens or antibodies. Allergic reactions can occur if the recipient is sensitive to one of these additives (e.g., mercurials, phenols, albumin, glycine).

Adjuvants

Many antigens evoke insufficient immunologic responses when given in their natural state. Efforts to enhance immunogenicity include mixing antigens with a variety of substances or adjuvants (e.g., aluminum adjuvants such as aluminum phosphate).

ROUTE, SITE, AND TECHNIQUE OF IMMUNIZATION

Route

Routes of administration are recommended for each immunobiologic. To avoid unnecessary local or systemic effects and/or to ensure optimal efficacy, the practitioner should not deviate from the recommended routes. Vaccines containing adjuvants must be injected deep into the muscle mass; they should not be administered subcutaneously or intradermally because they can cause local irritation, inflammation, granuloma formation, or necrosis. Site Injectable immunobiologics should be administered where there is little likelihood of local, neural, vascular, or tissue injury. Subcutaneous injections are usually administered into the thigh of infants and in the deltoid area of older children and adults. Intradermal injections are generally given on the volar surface of the forearm except for human diploid cell rabies vaccine with which reactions are less severe in the deltoid area. The preferred sites for intramuscular injections are the anterolateral aspect of the upper thigh and the deltoid muscle of the upper arm. In most infants, the anterolateral aspect of the thigh provides the largest muscle mass and is therefore the preferred site. An individual decision must be made for each child based on the volume of the material to be administered and the size of the muscle into which it is to be injected. In adults, the deltoid is recommended for routine intramuscular vaccine administration, particularly for hepatitis B vaccine. The buttock should not be used routinely as a vaccination site for infants, children, or adults because of the risk of injury to the sciatic nerve. In addition, injection into the buttock has been associated with decreased immunogenicity of hepatitis B and rabies vaccines, presumably because of inadvertent subcutaneous injection or injection into deep fat tissue. If the buttock is used when very large volumes are to be injected or multiple doses are necessary (e.g., large doses of IG), the central region should be avoided; only the upper, outer quadrant should be used.

Techniques

Syringes and needles used for injections must be sterile and preferably disposable to minimize the risk of contamination. For an intramuscular injection, the needle and syringe

should be of sufficient length and bore to reach the muscle mass itself and prevent vaccine from seeping into subcutaneous tissue. For children, a 20- or 22-gauge needle 1 to 1-1/2 inches long is recommended. For small infants, a 25-gauge 5/8-inch-long needle may be adequate. For adults, the suggested needle length is 1-1/2 inches. For subcutaneous or intradermal injections, a 25-gauge needle 5/8-3/4 inches long is recommended.

Before the injection is given, the needle is inserted in the site and the syringe plunger pulled back; if blood appears, the needle should be withdrawn and a new site selected. The process should be repeated until no blood appears. A separate needle and syringe should be used for each vaccine injected. Disposable needles and syringes should be discarded into labeled, puncture-proof containers to prevent accidental needlesticks or reuse. If more than one vaccine preparation is administered or if vaccine and IG are administered simultaneously, each should be given at a different site.

DOSAGE

The recommendations on dosages of immunobiologics are derived from theoretical considerations, experimental trials, and clinical experience. Administration of volumes smaller than those recommended, such as split doses or intradermal administration (unless specifically recommended), can result in inadequate protection. Use of larger than the recommended dose can be hazardous because of excessive local or systemic concentrations of antigens.

The ACIP strongly discourages any variation from the recommended volume or number of doses of any vaccine. Some practitioners use smaller, divided, doses of vaccine, thereby reducing the total immunizing dose. Others use multiple smaller doses that together equal a full immunizing dose (e.g., diphtheria and tetanus toxoids and pertussis vaccine (DTP)) in an effort to reduce reactions. However, the serologic response, clinical efficacy, and/or frequency and severity of adverse reactions of such schedules have not been adequately studied.

AGE AT WHICH IMMUNOBIOLOGICS ARE ADMINISTERED

Several factors influence recommendations concerning the age at

which vaccines are administered; they are age-specific risks of disease, age-specific risks of complications, ability of persons of a given age to respond to the vaccine(s), and potential interference with the immune response by passively transferred maternal antibody. In general, vaccines are recommended for the youngest age group at risk whose members are known to develop an acceptable antibody response to vaccination.

SPACING OF IMMUNOBIOLOGICS **Multiple Doses of Same Antigen**

Some products require administration of more than one dose for development of an adequate antibody response. In addition, some products require periodic reinforcement (booster) doses to maintain protection. In recommending the ages and/or intervals for multiple doses, the ACIP takes into account risks from disease and the need to induce or maintain satisfactory protection.

Intervals between doses that are longer than those recommended do not lead to a reduction in final antibody levels. Therefore, it is not necessary to restart an interrupted series of an immunobiologic or to add extra doses.

In contrast, giving doses of a vaccine or toxoid at less than recommended intervals may lessen the antibody response and therefore should be avoided. Doses given at less than recommended intervals should not be counted as part of a primary series.

Some vaccines produce local or systemic symptoms in certain recipients when given too frequently (e.g., Td, DT, and rabies). Such reactions are thought to result from the formation of antigen-antibody complexes. Good recordkeeping, careful patient histories, and adherence to recommended schedules can decrease the incidence of such reactions without sacrificing immunity.

Different Antigens

Experimental evidence and extensive clinical experience have strengthened the scientific basis for giving certain vaccines at the same time. Many of the widely used vaccines can safely and effectively be given simultaneously (i.e., on the same day, not at the same site). This knowledge is particularly helpful when there is imminent exposure to several infectious diseases, preparation for foreign travel, or uncertainty that the person

will return for further doses of vaccine.

1. Simultaneous Administration

In general, inactivated vaccines can be administered simultaneously at separate sites. However, when vaccines commonly associated with local or systemic side effects (e.g., cholera, typhoid, and plague) are given simultaneously, the side effects can be accentuated. Whenever possible, these vaccines should be given on separate occasions.

Simultaneous administration of pneumococcal polysaccharide vaccine and whole-virus influenza vaccine elicits satisfactory antibody responses without increasing the incidence or severity of adverse reactions. Simultaneous administration of the pneumococcal vaccine and split-virus influenza vaccine can also be expected to yield satisfactory results. Influenza vaccine should be administered annually to the target population. In general, simultaneous administration of the most widely used live and inactivated vaccines has not resulted in impaired antibody responses or increased rates of adverse reactions. Administration of combined measles, mumps, and rubella (MMR) vaccine yields results similar to administration of individual measles, mumps, and rubella vaccines at different sites. Therefore, there is no medical basis for giving these vaccines separately for routine immunization instead of the preferred MMR combined vaccine.

There are equivalent antibody responses and no clinically significant increases in the frequency of adverse events when DTP, MMR, and oral polio vaccine (OPV) or inactivated polio vaccine (IPV) are administered either simultaneously at different sites or separately. As a result, routine simultaneous administration of MMR, DTP, and OPV (or IPV) to all children greater than or equal to 15 months who are eligible to receive these vaccines is recommended. Administration of MMR at 15 months followed by DTP and OPV (or IPV) at 18 months remains an acceptable alternative, especially for children with caregivers known to be generally compliant with other health-care recommendations. Data are lacking on concomitant administration of Haemophilus influenzae b conjugate vaccine (HbCV) or Haemophilus influenzae b polysaccharide vaccine (HbPV) and MMR and

OPV vaccine. If the child might not be brought back for future immunizations, the simultaneous administration of all vaccines (including DTP, OPV, MMR, and HbCV or HbPV) appropriate to the age and previous vaccination status of the recipient is recommended. Hepatitis B vaccine given with DTP and OPV or given with yellow fever vaccine is as safe and efficacious as these vaccines administered separately.

The antibody responses of both cholera and yellow fever vaccines are decreased if given simultaneously or within a short time of each other. If possible, cholera and yellow fever vaccinations should be separated by at least 3 weeks. If there are time constraints and both vaccines are necessary, the injections can be given simultaneously or within a 3-week period with the understanding that antibody response may not be optimal. Decisions on the need for yellow fever and cholera immunizations should take into account the amount of protection afforded by the vaccine, the possibility that environmental or hygienic practices may be sufficient to avoid disease exposure, and the existence of vaccination requirements for entry into a country.

2. Nonsimultaneous Administration

Inactivated vaccines do not interfere with the immune response to other inactivated vaccines or to live vaccines except, as noted above, with cholera and yellow fever vaccines. In general, an inactivated vaccine can be given either simultaneously or at any time before or after a different inactivated vaccine or a live vaccine.

There are theoretical concerns that the immune response to one live-virus vaccine might be impaired if given within 30 days of another. Whenever possible, live-virus vaccines not administered on the same day should be given at least 30 days apart.

Live-virus vaccines can interfere with the response to a tuberculin test. Tuberculin testing can be done either on the same day that live-virus vaccines are administered or 4-6 weeks afterwards.

Immune Globulin

If administration of an IG preparation becomes necessary because of imminent exposure to disease, live-virus vaccines can be given simulta-

neously with the IG product, with the recognition that vaccine-induced immunity might be compromised. The vaccine should be administered at a site remote from that chosen for the IG inoculation. Vaccination should be repeated about 3 months later unless serologic testing indicates that specific antibodies have been produced. OPV and yellow fever vaccines are exceptions, however, and are not affected by administration of IG at any time.

Live, attenuated vaccine viruses might not replicate successfully, and antibody response could be diminished when the vaccine is given after IG or specific IG preparations. Whole blood or other antibody-containing blood products can interfere with the antibody response to measles, mumps, and rubella vaccines. In general, these parenterally administered live vaccines should not be given for at least 6 weeks, and preferably 3 months, after IG administration. However, the postpartum vaccination of susceptible women with rubella vaccine should not be delayed because of receipt of anti-Rho(D) IG (human) or any other blood product during the last trimester of pregnancy or at delivery. These women should be vaccinated immediately after delivery and, if possible, tested in 3 months to ensure that rubella immunity was established.

If administration of IG preparations becomes necessary after a live-virus vaccine has been given, interference can occur. Usually, vaccine virus replication and stimulation of immunity will occur 1-2 weeks after vaccination. Thus, if the interval between administration of live-virus vaccine and subsequent administration of an IG preparation is less than 14 days, vaccination should be repeated at least 3 months after the IG product was given, unless serologic testing indicates that antibodies were produced.

In general, there is little interaction between IG preparations and inactivated vaccines. Therefore, inactivated vaccines can be given simultaneously or at any time before or after an IG product is used. For example, postexposure prophylaxis with simultaneously administered hepatitis B, rabies, or tetanus IG and the corresponding inactivated vaccine or toxoid does not impair the immune response and provides immediate protection and long-lasting immunity. The vaccine and IG should be given at different sites, and standard doses of the corresponding vaccine should be used. Increasing the

vaccine dose volume or number of immunizations is not indicated.

HYPERSENSITIVITY TO VACCINE COMPONENTS

Vaccine components can cause allergic reactions in some recipients. These reactions can be local or systemic, including mild to severe anaphylaxis (e.g., hives, swelling of the mouth and throat, difficulty breathing, hypotension, or shock). The responsible vaccine components can derive from: 1) animal protein, 2) antibiotics, 3) preservatives, and 4) stabilizers. The most common animal protein allergen is egg protein found in vaccines prepared using embryonated chicken eggs or chicken embryo cell cultures (e.g., yellow fever, mumps, measles, and influenza vaccines). Ordinarily, persons who are able to eat eggs or egg products safely can receive these vaccines; persons with histories of anaphylactic allergy to eggs or egg proteins should not.

Asking persons whether they can eat eggs without adverse effects is a reasonable way to screen for those who might be at risk from receiving measles, mumps, yellow fever, and influenza vaccines. Protocols requiring extreme caution have been developed for testing and vaccinating with measles and mumps vaccines those persons with anaphylactic reactions to egg ingestion.² A regimen for administering influenza vaccine to children with egg hypersensitivity and severe asthma has also been developed.³

Rubella vaccine is grown in human diploid cell cultures and can safely be given to persons with histories of severe allergy to eggs or egg proteins.

Some vaccines contain trace amounts of antibiotics to which patients may be hypersensitive. The information provided in the vaccine package insert should be carefully reviewed before a decision is made whether the rare patient with such hypersensitivity should be given the vaccine(s). No currently recommended vaccine contains penicillin or its derivatives.

MMR and its individual component vaccines contain trace amounts of neomycin. Although the amount present is less than would usually be used for the skin test to determine hypersensitivity, persons who have experienced anaphylactic reactions to neomycin should not be given these vaccines. Most often, neomycin allergy is a contact dermatitis, a manifestation of a

delayed-type (cell-mediated) immune response rather than anaphylaxis. A history of delayed-type reactions to neomycin is not a contraindication for these vaccines.

Bacterial vaccines, such as cholera, DTP, plague, and typhoid, are frequently associated with local or systemic adverse effects, such as redness, soreness, and fever. These reactions are difficult to link with a specific sensitivity to vaccine components and appear to be toxic rather than hypersensitive. On rare occasions, urticarial or anaphylactic reactions in DTP, DT, or Td recipients have been reported. When such events are reported, appropriate skin tests should be performed to determine sensitivity to tetanus toxoid before its use is discontinued.⁴

ALTERED IMMUNOCOMPETENCE

Virus replication after administration of live, attenuated-virus vaccines can be enhanced in persons with immunodeficiency diseases and in persons with suppressed capacity for immune response as occurs with leukemia, lymphoma, generalized malignancy, symptomatic HIV infections, or therapy with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids. Severe complications have followed vaccination with live, attenuated-virus vaccines and with live-bacteria vaccines (e.g., BCG) in patients with leukemia, lymphoma, or suppressed immune responses. In general, these patients should not be given live vaccines, with the exceptions noted below.

If polio immunization is indicated for immunosuppressed patients, their household members, or other close contacts, these persons should be given IPV rather than OPV. Although a protective immune response cannot be assured in the immunocompromised patient, some protection may be provided. Because of the possibility of immunodeficiency in other children born to a family in which one such case has occurred, no family members should receive OPV unless the immune statuses of the intended recipient and all other children in the family are known.

Patients with leukemia in remission whose chemotherapy has been terminated for at least 3 months can be given live-virus vaccines. Short-term, low-to-moderate dose systemic corticosteroid therapy (less than 2 weeks), topical steroid therapy (e.g., nasal,

skin), long-term alternate-day treatment with low to moderate doses of short-acting systemic steroids, and intra-articular, bursal, or tendon injection with corticosteroids are not immunosuppressive in their usual doses and do not contraindicate live-virus vaccine administration.

The growing number of infants and preschoolers infected with HIV has directed special attention to the appropriate immunization of such children. The evaluation and testing for HIV infection of asymptomatic children presenting for vaccines is not necessary before decisions concerning immunization are made. The inactivated childhood vaccines (e.g., DTP or HbCV) should be given to HIV-infected children regardless of whether HIV symptoms are present. Although OPV has not been harmful when administered to asymptomatic HIV-infected children, IPV is the vaccine of choice if the child is known to be infected. The use of IPV not only eliminates any theoretical risk to the vaccinee but also prevents the possibility of vaccine virus spread to immunocompromised close contacts. Asymptomatically infected persons in need of MMR should receive it. Also, MMR should be considered for all symptomatic HIV-infected children since measles disease can be severe in symptomatic HIV-infected children. Limited studies of MMR immunization in both asymptomatic and symptomatic HIV-infected patients have not documented serious or unusual adverse events. In addition, pneumococcal vaccine is recommended for any child infected with HIV. Influenza vaccine is recommended for children with symptoms of HIV infection.

FEBRILE ILLNESS

The decision to administer or delay vaccination because of a current or recent febrile illness depends largely on the severity of symptoms and on the etiology of the disease.

Although a moderate or severe febrile illness is reason to postpone immunizations, minor illnesses such as mild upper-respiratory infections (URI) with or without low-grade fever are not contraindications for vaccination. In persons whose compliance with medical care cannot be assured, it is particularly important to take every opportunity to provide appropriate vaccinations.

Children with moderate or severe febrile illnesses can be vaccinated as

soon as the child has recovered. This precaution to wait avoids superimposing adverse effects of the vaccine on the underlying illness or mistakenly attributing a manifestation of the underlying illness to the vaccine.

Routine physical examinations or measuring temperatures are not prerequisites for vaccinating infants and children who appear to be in good health. Asking the parent or guardian if the child is ill, postponing vaccination in those with moderate or severe febrile illnesses, and immunizing those without contraindications to vaccination are appropriate procedures in childhood immunization programs.

VACCINATION DURING PREGNANCY

Because of a theoretical risk to the developing fetus, pregnant women or women likely to become pregnant within 3 months after vaccination should not be given live, attenuated-virus vaccines. With some of these vaccines—particularly rubella, measles, and mumps—pregnancy is a contraindication. Both yellow fever vaccine and OPV, however, can be given to pregnant women who are at substantial risk of exposure to natural infection. When a vaccine is to be given during pregnancy, waiting until the second or third trimester is a reasonable precaution to minimize concern over teratogenicity. Although there are theoretical risks, there is no evidence of congenital rubella syndrome in infants born to susceptible mothers who inadvertently were given rubella vaccine during pregnancy.

Persons given measles, mumps, or rubella vaccines can shed but not transmit these viruses. These vaccines can be administered safely to the children of pregnant women. Although live polio virus is shed by persons recently immunized with OPV (particularly after the first dose), this vaccine can also be administered to the children of pregnant women because experience has not revealed any risk of polio vaccine virus to the fetus.

There is no convincing evidence of risk to the fetus from immunizing the pregnant woman with inactivated virus or bacteria vaccines or toxoids. Previously immunized pregnant women who have not received a Td immunization within the last 10 years should receive a booster dose once past the first trimester. Women who are unimmunized or only partially immunized against tetanus should complete

as much of the primary series as possible during the last two trimesters of the pregnancy. Depending on when the woman seeks prenatal care and the required interval between doses, one or two doses of Td can be administered before delivery. Eligible women who do not complete the required three-dose series during pregnancy should be followed after delivery to assure they receive the doses necessary for protection.

All pregnant women should be evaluated for immunity to rubella. Women susceptible to rubella should be immunized immediately after delivery. In addition, a woman's status as a carrier of hepatitis B should also be assessed during pregnancy. A woman infected with hepatitis B virus should be followed carefully so that her child can receive HBIG and the hepatitis B vaccine series shortly after delivery. There is no known risk to the fetus from passive immunization of pregnant women with IG. Further information regarding immunization of pregnant women is available in the American College of Obstetricians and Gynecologists Technical Bulletin Number 64, May 1982.

MISCONCEPTIONS CONCERNING CONTRAINDICATIONS TO VACCINATION

Some health-care providers inappropriately consider certain conditions or circumstances contraindications to vaccination. Conditions most often inappropriately regarded as routine contraindications include the following:

1. Reaction to a previous dose of DTP vaccine that involved only soreness, redness, or swelling in the immediate vicinity of the vaccination site or temperature of less than 105 F (40.5 C).
2. Mild acute illness with low-grade fever or mild diarrheal illness in an otherwise well child.
3. Current antimicrobial therapy or the convalescent phase of illnesses.
4. Prematurity. The appropriate age for initiating immunizations in the prematurely born infant is the usual chronologic age. Vaccine doses should not be reduced for preterm infants.
5. Pregnancy of mother or other household contact.
6. Recent exposure to an infectious disease.
7. Breastfeeding. The only vaccine virus that has been isolated from breast milk is rubella vaccine virus. There is no good evidence that breast milk from

women immunized against rubella is harmful to infants.

8. A history of nonspecific allergies or relatives with allergies.

9. Allergies to penicillin or any other antibiotic, except anaphylactic reactions to neomycin (e.g., MMR-containing vaccines) or streptomycin (e.g., OPV). None of the vaccines licensed in the United States contain penicillin.

10. Allergies to duck meat or duck feathers. No vaccine available in the United States is produced in substrates containing duck antigens.

11. Family history of convulsions in persons considered for pertussis or measles vaccination.^{5,6}

12. Family history of sudden infant death syndrome in children considered for DTP vaccination.

13. Family history of an adverse event, unrelated to immunosuppression, following vaccination.

ADVERSE EVENTS FOLLOWING VACCINATION

Modern vaccines are safe and effective but not completely so. Adverse events have been reported following the administration of all vaccines. These events range from frequent, minor, local reactions to extremely rare, severe, systemic illness, such as paralysis associated with OPV. It is often impossible to establish evidence for cause-and-effect relationships when untoward events occur after vaccination because temporal association alone does not necessarily indicate causation. More complete information on adverse reactions to a specific vaccine may be found in the ACIP recommendations for each vaccine.

The National Vaccine Injury Compensation Program established by the National Childhood Vaccine Injury Act of 1986 requires physicians and other health-care providers who administer vaccines to maintain permanent immunization records and to report occurrences of certain adverse events to the U.S. Department of Health and Human Services. Recording and reporting requirements took effect on March 21, 1988. Reportable reactions include those listed in the Act for each vaccine^{7,8} and events specified in the manufacturer's vaccine package insert as contraindications to further doses of that vaccine. Although there will be one system for reporting adverse events following immunizations in the future, at present there are two separate systems. The

appropriate method depends on the source of funding used to purchase the vaccine. Events that occur after receipt of a vaccine purchased with public (federal, state, and/or local government) funds must be reported by the administering health provider to the appropriate local, county, or state health department. The state health department completes and submits the correct forms to CDC. Reportable events that follow administration of vaccines purchased with private money are reported by the health-care provider directly to the Food and Drug Administration (FDA).

PATIENT INFORMATION

Parents, the responsible caregiver, or adult patients should be informed about the benefits and risks of vaccine in understandable language. Ample opportunity for questions and answers should be provided before each immunization. CDC has developed "Important Information Statements" for use with federally purchased vaccines given in public health clinics, but similar statements have not been universally adopted for the private medical-care sector.

An Important Information Statement must be developed for each vaccine covered by the National Childhood Vaccine Injury Act (DTP or component antigens, MMR or component antigens, IPV, and OPV). These statements are to be used by all public and private providers of vaccines. Until the Important Information Statements established by the Act become available the current CDC Important Information Statements should be used in public health clinics and other settings where publicly purchased vaccines are used. The use of similar statements in the private sector is encouraged.

VACCINE PROGRAMS

The best way to reduce vaccine-preventable diseases is to have a highly immune population. Universal immunization is an important part of good health care and should be accomplished through routine and intensive programs carried out in physicians' offices and in public health clinics. Programs aimed at ensuring that all children are immunized at the recommended ages should be established and maintained in all communities. In addition, appropriate immunizations should be available for all adults.

Every visit to a health-care provider

is an opportunity to update a patient's immunization status with needed vaccines. All adults should complete a primary series of tetanus and diphtheria toxoids, then receive a booster dose every 10 years. Persons greater than or equal to 65 years old and all adults with medical conditions that place them at risk for pneumococcal disease or serious complications of influenza should receive one dose of pneumococcal polysaccharide vaccine and annual injections of influenza vaccine. In addition, immunization programs for adults should provide MMR vaccine whenever possible to anyone believed susceptible to measles, mumps, or rubella. Use of MMR ensures that the recipient has been immunized against three different diseases and causes no harm if the vaccinee is already immune to one or more of its components.

Official health agencies should take necessary steps, including developing and enforcing school immunization requirements, to assure that students at all grade levels, including college students, and those in child-care centers are protected against vaccine-preventable diseases. Agencies should also encourage institutions such as hospitals and extended-care facilities to adopt policies regarding the appropriate immunization of residents and employees.

Dates of immunization (day, month, and year) should be recorded on institutional immunization records, such as those kept in schools and child-care centers. This will facilitate assessments that a primary vaccine series has been completed according to an appropriate schedule and that needed boosters have been obtained at the correct time.

Tickler or recall systems can identify children who are due for immunizations or are behind schedule so parents can be contacted and reminded to have their children immunized. The ACIP recommends the use of these systems by all health-care providers. Such systems should also be developed by health-care providers who treat adults to ensure that at-risk persons receive influenza vaccine annually.

IMMUNIZATION RECORDS

Documentation of patient immunizations will help ensure that persons in need of vaccine receive it and that adequately vaccinated patients are not overimmunized with increased risk of hypersensitivity (e.g., tetanus toxoid hypersensitivity).

Patient's Personal Record

Official immunization cards have been adopted by every state and the District of Columbia to encourage uniformity of records and to facilitate the assessment of immunization status by schools and child-care centers. The records are also important tools in immunization education programs aimed at increasing parental and patient awareness of the need for vaccines. A permanent immunization record card should be established for each newborn infant and maintained by the parent. In many states, these cards are distributed to new mothers before discharge from the hospital.

Provider Records

The National Vaccine Injury Compensation Program requires each health-care provider to record in the vaccine recipient's permanent medical record (or in a permanent office log or file) the provider's name, address, and title (if appropriate), the type of immunobiologic administered, the manufacturer, lot number, and date of administration. Health-care provider is any licensed health-care professional, organization, or institution, whether private or public (including federal, state, and local departments and agencies), under whose authority a specified vaccine is administered. The vaccines covered under this new law include: DTP and MMR (or any of their components given singly or in combination), OPV, and IPV. A permanent immunization record should also be established and maintained for adults and children who receive vaccines not covered by the National Vaccine Injury Act. The ACIP recommends use of standard records that note the type, manufacturer, lot number, and date of administration for each immunobiologic administered. Serologic test results for vaccine-preventable diseases, such as those for rubella screening, as well as documented episodes of adverse events, should also be recorded in the vaccine recipient's permanent medical record.

SOURCES OF VACCINE INFORMATION

In addition to these general recommendations, the practitioner can draw on a variety of sources for specific data and updated information including: Official vaccine package circulars. Man-

ufacturer-provided product-specific information approved by the FDA with each vaccine. Some of these materials are reproduced in the Physician's Desk Reference (PDR).

Morbidity and Mortality Weekly Report (MMWR). Published weekly by CDC, MMWR contains regular and special ACIP recommendations on vaccine use and statements of vaccine policy as they are developed and reports of specific disease activity. Subscriptions are available through Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402. Also available through MMS Publications, C.S.P.O. Box 9120, Waltham, MA 02254.

Health Information for International Travel. Booklet published annually by CDC as a guide to national requirements and with recommendations for specific immunizations and health practices for travel to foreign countries. Purchase from the Superintendent of Documents (address above).

Advisory memoranda are published as needed by CDC to advise international travelers or persons who provide information to travelers about specific outbreaks of communicable diseases abroad. They include health information for prevention and specific recommendations for immunization. Memoranda and/or placement on mailing list are available from Division of Quarantine, Center for Prevention Services (CPS), CDC, Atlanta, GA 30333.

The Report of the Committee on Infectious Diseases of the American Academy of Pediatrics (Red Book). This report, which contains recommendations on all licensed vaccines, is updated every 2-3 years, most recently in 1988. Policy changes for individual recommendations for immunization practices are published as needed by the American Academy of Pediatrics in the journal *Pediatrics*. They are available from American Academy of Pediatrics, Publications Division, 141 Northwest Point Blvd., P.O. Box 927, Elk Grove Village, IL 60009-0927.

Control of Communicable Diseases in Man is published by the American Public Health Association every 5 years, most recently in 1985 (14th ed.) The manual contains information about infectious diseases, their occurrence worldwide, diagnoses and therapy, and up-to-date recommendations on isolation and other control meas-

ures for each disease presented. It is available from the American Public Health Association, 1015 Fifteenth St. N.W., Washington, DC 20005.

Guide for Adult Immunization (1985) is produced by the American College of Physicians for physicians caring for adults. It emphasizes use of vaccines in healthy adults and adults with specific disease problems. It is available from American College of Physicians, Division of Scientific Activities, Health and Public Policy, 4200 Pine Street, Philadelphia, PA 19104.

Technical bulletins of the American College of Obstetricians and Gynecologists are updated periodically. These bulletins contain important information on immunization of pregnant women. They are available from American College of Obstetricians and Gynecologists, Attention: Resource Center, 409 12th Street S.W., Washington, DC 20024-2188.

State and many local health departments frequently provide technical advice, printed information on vaccines and immunization schedules, posters, and other educational materials.

Division of Immunization, CPS, CDC, Atlanta, GA 30333, telephone (404) 639-3311, offers technical advice on vaccine recommendations, disease outbreak control, and sources of immunobiologics. In addition, a course on the epidemiology, prevention, and control of vaccine preventable diseases is offered each year in Atlanta and, on occasion, in different states.

The Editorial Board Speaks . . .

Milton Arnold, MD

In his tenure with us, Milt has more than earned our respect and admiration. He has worked tirelessly on the many tasks assigned to him and completed them with dispatch. Our previous biographical sketch (*AJDC*. 1987;141:610) outlined his many accomplishments. Added to these is a new grandchild, of whom he and Sylvia are justifiably proud and indulgent. He has one of the most active "retirements" of anyone I've known.

His contribution below is particularly cogent for today's generation of physicians. Not "born" to the computer age, many of us have had to struggle to get there, as we watched our youngsters flip through the keys and master the technology with little discomfort or distress. Milt captures the sentiments of many as he describes a new marriage, one that he falsely claims "threatens" his longer and much happier one. Many of our readers will recognize his feelings. Enjoy!

COMPUTER TIMIDITY: SOME THOUGHTS

Can a long-existing marriage survive the presence of a computer? In sickness and in health, for better or for worse, until death do you part; nowhere in our 39-year-old Katuba (marriage contract) is there mention of a computer and it's potential for inanimate infidelity and occasional bouts of manic-depressive behavior.

The courtship between the computer and me was long and stormy. It was full of distrust, intimidation, and frustration. The generational gap was evident. My godchild, at 5 years of age, was studying English and Spanish grammar on her Apple computer. My three score plus years provided little more than confusion.

Age alone should entitle me to some seniority and wisdom, but this device created by the "Baby Boomers" was their consummate revenge. "Never trust anyone under 60."

With the computer, there developed a whole new vocabulary designed to confound: BITS, BYTES, RAM, ROM, DOS, D-BASE—certainly enough new acronyms to create a rebirth of the "New Deal." Other words that were familiar now had new definitions: mouse, floppy, default, icons, menu, wraparound, and the ever-present euphemism, "user friendly." The teachers of this new craft seemed hardly old enough to shave (cheeks or legs), and their demeanor, albeit friendly, was confrontational to this naive mind. I could procrastinate no longer since I was well overdue for my midlife change. The computer would reluctantly be accepted along with other less palatable modifications in my life-style, such as low-cholesterol meals and exercise. The MacIntosh joined our family.

For historical clarity, let it be known that my office had been computerized for more than two decades for fiduciary purposes. It was plethoric with an accumulation of reams of printed numbers, which were saved for reasons not yet clear. My relationship with that computer was both suspect and via an intermediary.

I now have a personal computer (PC), which suggests some sort of an intimate relationship, and there has been no third party to referee or mediate our disputes. This is somewhat akin to child rearing without the annoyance of Pampers. In both cases, one tries to share a common language, ask and answer questions, establish authority, and gain satisfaction in molding the resulting product. The computer assumes human qualities. At times it makes impudent comments, cajoles, and asks threatening questions that suggest Armageddon is not far off. My PC has icons that smile or pout depending on my actions.

Eventually, one succumbs to the challenge. Marital obligations are threatened as the "USER" works late into the night to gain control or find the information that has disappeared from the monitor due to some ill-chosen command. Like Walter Mitty, I changed personas and found myself in the airport tower moving words and phrases in lieu of wide-body jets. Even in my imagination, I lacked modernity. The contemporary Mitty would be Captain James T. Kirk on the *Starship Enterprise*.

There is some time spent in experiential learning until one feels confident that the computer understands the limits of its turf and our mutual pecking order. The latter is short-lived, and periodic "flash-backs" are inevitable.

The word processor permits even the most unskilled typist to swiftly correct errors, reroute whole paragraphs, or place them on hold until their presence is requested. Inept decisions are avoided by bells associated with comments like, "Are you sure you want to discard this paragraph?" It makes one pause and think about a previous action or at least question the computer's assertiveness. The machine is addictive, and with the almost limitless supply of innovative software, more and more tasks are assigned to it. Chores, such as consulting a dictionary or thesaurus, are accomplished by touching a couple of keys.

The PC has broadened my options for continuing medical education by accessing the literature rapidly and precisely. The addition of a modem provides such convenience at the time and place of one's choosing. Merely furnish the computer with any of the following to initiate a literature search: subject, author (if you have a preference), any limitations you may wish to include (age, gender, language, range of years to be reviewed), and shortly there appears on the screen abstracts of articles from which you may select. The whole process takes minutes, even for the unskilled. The PC leads you through the sequence, and no complex series of commands must be memorized.

Computer graphics enable the production of inexpensive slides and most printed materials from newsletters to personalized anniversary cards, which endears the PC to the family who wonders where your leisure hours are spent.

Remember, it is not necessary to understand a computer to use it. Computer intimidation and humiliation subside when the owner recognizes this is but a machine, invented by humans, and thus far subject to their control . . . perhaps.

Computers in Medicine

Augmenting Medical Care in Pediatric Patients With Chronic Illnesses

Eric G. Handler, MD, MPH

• The use of computers to aid care for chronically ill pediatric patients is a relatively new concept. We are currently using Filemaker II software and a Macintosh Plus computer to augment overall patient care in children with chronic diseases, such as spina bifida, cerebral palsy, neuromuscular diseases, head injury, and spinal cord injury. This is a computerized medical record with a clinical database for dissemination of information to multidisciplinary team members, generating letters to private health care providers, displaying telephone messages, and assisting inpatient care. Advances in computer technology will provide future applications to aid health care providers in caring for patients with chronic illnesses.

(AJDC. 1989;143:1021-1023)

Computers have been used for medical purposes for several years in the administrative, business, and laboratory fields. However, personal computers have had limited applications in direct patient care for outpatients as well as inpatients.¹⁻³ We are currently utilizing a personal computer for direct patient care in our pediatric rehabilitation population. The benefits are boundless, and with continued rapid technological advances, further applications will be identified.

MATERIALS AND METHODS

Equipment

Computer System.—We use an Apple Macintosh Plus personal computer (Apple Computer Inc, Cupertino, Calif) with 1 megabyte of random-access memory and a 20-megabyte hard disk.

Software.—We use Filemaker II (Claris

Corp, Mountain View, Calif), a flat file database (not a relational structure) that has multiuser capabilities. The program has multiuser and network capabilities.

Printer.—We use an Imagewriter II printer (Apple Computer Inc).

Terminology and Definitions

A *file* is a Macintosh document. A *record* is all the information about one item, person, or transaction. A file is composed of any number of records containing data. The individual components of a record are *fields*. A *layout* is an arrangement of objects that can be used to control the way information looks on the screen and on paper. Each layout is completely separate from the data; the layout controls the appearance, not the content.

Methods

The basic layout for the computerized medical record was developed in approximately 1 hour. Modifying the layouts for different clinics required less than 15 minutes. The layouts can be accessed by simple menu operations or by scripts that expedite the process by using keyboard commands.

Depending on the amount of material contained in a given layout, information can be entered rather quickly even when using a two-finger typing technique. Approximately 5 minutes is needed to update the computer information obtained during the patient's return visits. Initial and new visits require more time, and information is entered directly into the computer by the physician after clinic hours.

Fig 2.—Spinal cord injury layout.

COMMENT

We currently have information on approximately 250 pediatric rehabilitation patients entered in the flat file database Filemaker II. There are several patient diagnostic categories: spina bifida, cerebral palsy, head injury, neuromuscular diseases, and spinal cord injury. These children have a multitude of complex problems requiring a multidisciplinary team approach to help in their management. Our team consists of a pediatrician, pediatric rehabilitation psychologist, nurse, physical and occupational therapists, medical social worker, and several subspecialists, such as a neurosurgeon, orthopedist, and urologist.

The type of program layout implemented depends on the patient's diagnosis. For example, Fig 1 demonstrates the layout for the spina bifida clinic. Each patient's record includes several sections consisting of different fields: general patient information, problem-oriented records containing current

medical evaluations and examinations, physical examination, and clinic recommendations. Each field contains previous laboratory test results as well as individual evaluations by the different team members.

A layout for patients with spinal cord injury contains slightly different informational fields (Fig 2). These patients can have significant pulmonary problems, so an additional field is added. However, the basic informational core remains unchanged.

A clinic review process occurs prior to the patient's visit, and team members are given copies of the patient's last computer-generated clinical record. This has several observed benefits: (1) Medical students, interns, and residents rotate through the clinic weekly. A standardized form allows for consistency in obtaining pertinent information during the patient's visit and provides a sense of continuity in overall patient care. (2) The families are not repeatedly asked the same questions by

different team members during a clinic visit. (3) Chart reviews are not necessary before the patient's visit. This allows more time to address the patient's present problems and concerns. (4) One does not have to rely on the hospital chart being available during the clinic visit. (5) Duplication of tests and ordering unnecessary laboratory work are less likely when all the previous laboratory test results are immediately available to all team members.

The patient information is manually updated on the worksheet and then directly entered into the computer. The record is printed on hospital stationery and placed directly into the chart within 2 days. A simple cover letter is sent to the private physician with a copy of the computerized clinical record. There is no longer a need to dictate notes on the patient's clinic visit. The clinic record is a single page, is easy to read, and contains only pertinent clinical information (Fig 3). Private practitioners have been grateful for being able to review this information quickly instead of having to read the normal lengthy dictations. The computer database can also generate a cover letter to the care provider that can include specific information directed to a physician specialty, such as orthopedics or neurosurgery. This is accomplished by linking fields in the letter layout with specific informational fields in another layout.

Another example of informational linking among layouts is the telephone message display (Fig 4). When a parent or patient calls the clinic, one can enter the patient's name into the name field, which results in immediate retrieval of selected patient information from the most recent clinic visit. The conversation is directly entered into the database and can become a permanent part of the patient's medical record. One does not have to wait until the medical records arrive before calling the family. This allows for quick return of calls, aids consistency in treatment, and decreases the potential for misunderstandings.

There are additional advantages to a computerized medical record. Every word entered into the individual fields is indexed so that this information can be readily retrieved for research, and further data manipulations can be performed by easily exporting the informa-

tion to statistical analysis computer programs. For example, we wanted to determine the number of spina bifida patients with diagnosed tethered cord. We evaluated the orthopedic, neurosurgical, and urologic consequences of untethering spinal cords as opposed to not performing this surgical procedure. The computer program allowed immediate access to this material. To obtain this

information by conventional means would have been extremely cumbersome and time-consuming.

Information that is of a sensitive or confidential nature can be hidden in the printout. The field box has a predefined number of lines, and words that extend beyond these boundaries appear only when the field is activated. When the clinic record is printed this material is

not shown, so clinic personnel do not have access to this information. This eliminates the need for keeping separate records for confidential materials, and when medical records are requested by different people or agencies, confidentiality is maintained.

The computer program is also applied to the pediatric rehabilitation inservice. Weekly updated printouts of hospital progress notes provide a summary of care. This is extremely helpful for several reasons: (1) Medical students, interns, and residents rotate on the inpatient service on a monthly basis. Pediatric rehabilitation inpatients can be admitted for as long as 6 months to a year, so review of chart information by the new team members would be a time-consuming task. (2) On-call teams have access to up-to-date information on the different rehabilitation patients. This provides a standardized level of knowledge for each patient. (3) Updated material on inpatient care requested by agencies and insurance companies can be retrieved. (4) Discharge summaries are no longer a lengthy organizational exercise.

Computer applications for inpatient and outpatient pediatric care augment overall pediatric rehabilitation patient care and allow medical personnel to spend more interactive time with the patients and their families. It is difficult to objectively assess the clinical impact of the computerized medical record on patient care, because the pediatric rehabilitation inpatient and outpatient service was in program development at the same time. However, unsolicited feedback from various health care providers (physicians, nurses, and therapists) has been highly favorable and has included numerous requests for instructional guidance on implementing similar programs in their areas of clinical practice. Computer technology is expanding rapidly, and this will undoubtedly have a direct impact on the practice of medicine in the future.

Cast Bronchitis in Infants and Children

Agustin Pérez-Soler, MD

• Seventy-two children (age range, 3 months to 5.5 years) with a clinical diagnosis of obstructive bronchitis (asthmoid or spastic bronchitis or bronchiolitis) were found to have bronchial casts in the gastric fluid, and in 2 additional cases casts were spontaneously expectorated in the bronchial exudate. Cast bronchitis had a long-term course of 10 to 24 months in 65 of the 74 patients. Common radiologic findings included bronchi presumably filled with secretions, areas of atelectasis, and lung emphysema of varying degrees. Cast bronchitis did not appear to be associated with eosinophilia and elevated serum IgE levels. Therefore, an extrinsic allergic mechanism is not likely involved in the pathogenesis of the condition. Bronchial casts had varying consistencies; although they were usually soft, they were sometimes rather hard. They were hollow, often ramified, and white and measured from 0.5 to 2 cm in length. Histologically, they consisted of metaplastic squamous epithelium with a varying degree of inflammatory cells and noncellular material. Some differences in biochemical composition were observed between bronchial casts and bronchial exudate of acute catarrhal bronchitis. No viruses could be isolated in 11 cast specimens. Our results suggest that cast formation is mainly related to the metaplastic transformation of the bronchial epithelium and that this metaplasia may play an important pathophysiologic role in certain infants and children with obstructive bronchitis.

(AJDC. 1989;143:1024-1029)

A form of bronchitis characterized by the production of an "organized" exudate that has the internal anatomic configuration of the respiratory tree has been repeatedly reported in adults. The expectoration of structures thought to be of a fibrinous or mucoidlike material

that are true bronchial casts rather than plugs of mucus (mucoid impaction) constitutes the differential sign of the disease.

There have been only a few reports of similar cases in children,¹⁻³ most likely because children swallow the respiratory secretions, and therefore the presence of bronchial casts can only consistently be proved by examination of the gastric fluid.

After observing two children (the first in 1942) with pronounced asthmatic symptoms who spontaneously expectorated evident tracheobronchial casts and had subsequent relief of symptoms, I hypothesized that cast formation might be a common phenomenon in infants and children with wheezing bronchitis (asthmoid or spastic bronchitis or bronchiolitis). During a long period of academic and private pediatric practice I obtained (with each family's consent) gastric fluid from 72 children who had repeated episodes of bronchitis, lasting at least 2 weeks but sometimes several months without clear remissions. Structures compatible with bronchial casts were found in all cases. The bronchial casts observed had varying consistencies; they were usually soft, although sometimes rather hard. They were hollow, often ramified, and white. My observations suggest that infants and children can be affected by an inflammatory process of the respiratory tract that results in expectoration of bronchial casts similar to the fibrinous bronchitis described years ago in adults.

A mild and chronic form of cast bronchitis is considered exceptionally rare, probably because the expectoration of bronchial exudates in children younger than 5 years of age is rare, and when it occurs the bronchial specimen is not routinely examined.

I report here on the clinical and radiologic characteristics of patients with

cast bronchitis and the microstructure and biochemical composition of the bronchial casts.

PATIENTS AND METHODS

Patients

Seventy-two children (age range, 3 months to 5.5 years) were found to have structures compatible with bronchial casts in the gastric fluid. Bronchial casts were also observed in two other children who spontaneously expectorated the bronchial secretions. All patients had symptoms of wheezing bronchitis for at least 2 weeks when they were studied. All patients were evaluated by clinical and radiologic methods. The presence of virus and the biochemical composition were investigated in bronchial casts obtained from 11 and 6 different patients, respectively. Three children older than 5 years of age with acute catarrhal bronchitis and spontaneous expectoration were used as controls in the biochemical composition studies.

Most patients included in this study were referred to me without a definite diagnosis after having been intensively evaluated at public and private hospitals and after failing to respond to conventional bronchodilator therapy.

Clinical and Laboratory Evaluation

A complete history was obtained and a physical examination was performed on all patients. All patients were followed up by me for at least 6 years after recovery. The routine radiologic and laboratory evaluation consisted of the following: posteroanterior and lateral chest roentgenograms, erythrocyte sedimentation rate, red and white blood cell counts, differential leukocyte count, and electrophoresis of serum proteins. The sweat test was performed in all 23 infants under 1 year of age and in 12 children older than 1 year who had suspicious chest roentgenogram findings. Immunoelectrophoresis and determination of serum IgE by the Prist method were performed in 8 patients. Salivary IgA levels were determined in 6 patients by immunonephelometry in the Department of Biochemistry, Ciudad Sanitaria de Barcelona, Spain. Normal serum IgE and salivary IgA values have been reported elsewhere.^{4,5}

Bronchial Cast Studies

Gastric Fluid Collection and Examination of Casts.—The gastric fluid was obtained by oral gastric suction (lavage with normal saline solution or hygienized water) early in the morning, within 15 minutes after the patient awakened. Gastric lavage was performed early in the morning to avoid obtaining bronchial secretions that had been exposed for a long time to gastric fluid digestion. On awakening, children cough and swallow the bronchial secretions accumulated during the night. If children do not cough for 45 minutes before awakening (time of transit through the stomach of small amounts of food), it is reasonable to assume that most bronchial secretions obtained by gastric lavage will have been in the stomach for the time elapsed between awakening and the performance of the gastric lavage. Only two children (4 and 5.5 years of age) spontaneously coughed up the bronchial secretions.

The gastric suction was performed using a Rüscher catheter No. 24 for infants and No. 28 for children (Willy Rüscher AG, Walblingen, West Germany). If a thinner catheter is used, the largest casts cannot be collected.

The gastric fluid obtained was routinely placed in a Petri dish to disperse the specimen. Under these conditions the morphologic characteristics of bronchial casts are easily displayed.

I was unable to study the effect of gastric fluid from normal control children on the bronchial secretions of children with acute catarrhal bronchitis because consent by parents was not granted. Neither could consent be obtained for the performance of bronchoscopies in patients with cast bronchitis.

Microscopic Studies.—All casts were studied cytologically and in 65 of 74 cases histologically.

Cytologic Studies.—Smears of bronchial exudate were stained using the methods of May, Grunwald, Giemsa, and Papanicolaou and observed under light microscopy.

Histologic Studies.—Bronchial casts were fixed in 10% formaldehyde and alcohol, embedded in paraffin, and stained with hematoxylin-eosin. Stains for fibrin and mucin were not performed because they are not specific.

Electron Microscopic Studies.—Electron microscopic studies were performed in three cases.

Biochemical Analysis.—The biochemical composition of bronchial casts from six patients was studied by simple radial immunodiffusion and electroimmunodiffusion techniques in the Department of Biochemistry, Ciudad Sanitaria de Barcelona. Results were compared with those obtained in three cases of acute catarrhal bronchitis in children whose bronchial secretions were spontane-

ously expectorated.

Isolation of Viruses.—Isolation of viruses by culture was attempted in cast specimens obtained from 11 patients in the Department of Microbiology, Faculty of Medicine, University of Barcelona.

RESULTS

Clinical Findings

The age at onset of disease ranged from 3 months to 5.5 years (90.4% of patients were between 6 months and 3 years of age). The initial clinical picture consisted of an acute episode of obstructive bronchitis in all cases; dyspnea of variable intensity and a mild to high temperature elevation of short duration were the main symptoms. Diffuse wheezing with some or abundant rales was heard in all patients. Signs of laryngeal involvement were mild or absent.

The time from the onset of symptoms to complete resolution was less than 3 months in the acute form of the disease (3 cases), between 3 and 9 months in the subacute form (6 cases), and more than 9 months in the chronic form (65 cases). No clear relationship between age and duration of disease was found.

No clinical signs of other conditions, such as pancreatic cystic fibrosis, previous foreign-body aspiration, esophageal reflux with esophagitis, or immunodeficiency, were observed. Only two cases were associated with other diseases, one with pancreatic cystic fibrosis and one with extrinsic asthma.

In patients with chronic cast bronchitis the course of the disease was characterized by variations in the intensity of the clinical symptoms over a period of 10 to 24 months; one child and one infant could not be considered cured until 33 months and 40 months after the onset of the condition, respectively. Wheezing was usually moderate, sometimes minimal, and, after the acute phase, a persisting cough that usually occurred in the morning, on awakening, was sometimes the only manifestation of the condition. No recurrences were observed beyond 2 months after the resolution of all symptoms. Dyspnea was initially more severe in patients with acute cast bronchitis than in patients with subacute or chronic cast bronchitis but tended to decrease dramatically early in the course of the disease, probably after the elimination of the first tracheobronchial casts.

Fig 1.—Basal bronchus occupied by bronchial cast, with some more aerated portions.

Fig 2.—Moderate lung hyperaeration and segmental atelectasis of the right lower lobe.

Radiologic Findings

Bronchi.—Partial occupation of the air space was sometimes clearly observed (Fig 1). Occupation of bronchi by secretions gave a clear cylindrical image rather than the lobulated or "botrioid" appearance associated with mucoid impaction in adults^{6,7} and with asthma⁸ and cystic fibrosis⁹ in children.

Lung Parenchyma.—Single or multiple areas of segmental, sometimes lobal, atelectasis were frequently observed (Figs 2 and 3). They usually lasted a few days, although occasionally they persisted for several weeks. Complete lung atelectasis¹ was not observed. Minimal areas of parenchymal consolidation corresponding to either small areas of atelectasis or peribronchial or perialveolar inflammation were also a common finding. Emphysematous changes of varying degree were

Fig 3. — Marked lung emphysema with shift of the mediastinum and two segmental atelectases, one in the right upper lobe (left) and the other in the left lower lobe (right).

Table 1. — Serum IgE Level, Blood Eosinophils, and Salivary IgA in Eight Patients With Cast Bronchitis

Patient No.	Age	Serum IgE, IU/mL	Blood Eosinophils, %	Salivary IgA, g/L
1	6 mo	33	2	...
2	2 y	18	12	...
3	3 y	6	4	0.173
4	2 y, 3 mo	250	4	0.050
5	3 y, 9 mo	161	4	0.085
6	5 y	14	2	0.090
7	5 y, 6 mo	5	3	0.010
8	2 y, 8 mo	20	6	0.050

observed in all cases, sometimes predominantly involving one hemithorax, with displacement of the heart and the mediastinum to the opposite side (Fig 3).

Laboratory Findings

The erythrocyte sedimentation rate and red and white blood cell counts were within normal limits in most cases. The leukocyte differential count consistently showed a mild lymphocytosis. In only 1 of 74 cases was there a marked eosinophilia, 35% in 1 case and 56% in the other. Neither of these 2 patients had a history of allergy, and allergic symptoms did not subsequently develop in either.

The serum protein profile was within normal limits in all patients in whom it was determined. No decrease in α_1 -globulin was observed. Serum IgE levels were normal in five of eight patients, moderately elevated in one, and mark-

edly elevated in two (Table 1). Salivary IgA levels were normal in three of six patients, slightly elevated in one, markedly elevated in one, and decreased in one (Table 1).

The sweat test was positive in only 1 of 23 children less than 1 year old and was negative in all 12 children more than 1 year old.

Bronchial Cast Studies

Physical Characteristics.—Casts obtained from patients with subacute and chronic cast bronchitis ranged from 0.5 to 2 cm in length and from 0.2 to 0.7 cm in diameter. They were normally cylindrical and often ramified. The largest casts were clearly hollow; the smallest had no apparent lumen because it was occluded by seromucous secretion, as shown by microscopic observation. Casts had varying consistencies; they were usually soft, sometimes rather hard, but never "fluid" like the muco-

purulent exudate of acute catarrhal bronchitis. They were white, sometimes light yellowish (Figs 4 and 5).

Apart from the cylindrical ramified casts, fragments of casts mixed with mucous and purulent material were also regularly observed. No Curchmann's spirals were seen in any case (macroscopically or microscopically).

Microscopic Structure.—The cytologic studies of bronchial cast smears showed the presence of an important epithelial component with a varying number of inflammatory cells (predominantly mononuclear cells in the chronic form) and noncellular fibrillar material in all cases. The epithelial component was not composed of cylindrical, ciliated-mucous epithelium as expected in the respiratory tract, but of squamous epithelium, sometimes with signs of keratinization.

The histologic study of sections of casts showed squamous metaplasia in all specimens (Figs 6 through 9). The metaplastic epithelium was the predominant cellular component in many cases. Casts composed preferentially or exclusively of metaplastic epithelium were stronger than casts with a relatively important inflammatory component (leukocytes, proteins).

Ultrastructural Changes.—No specific lesions could be assessed. The organelles, especially the mitochondria, appeared to be significantly damaged or destroyed. Organelle destruction may be due to peptic digestion by the gastric fluid or may be a manifestation of cellular degeneration, since the cells are not part of a vascularized tissue but of an exudate that is bound to necrosis.

Biochemical Composition.—Six specimens of bronchial casts were studied by radial immunodiffusion and electroimmunodiffusion. Results are shown in Table 2. Also shown in Table 2 are the results of an analysis of the biomedical composition of the bronchial secretion obtained from a representative patient with acute catarrhal bronchitis and spontaneous expectoration. Bronchial casts contained high-molecular-weight proteins, such as α_2 -macroglobulin and fibrin, that are quite viscous or that coagulate easily, while these proteins were not present or were present in smaller amounts in the bronchial exudate of patients with acute catarrhal

Fig 4.—Three bronchial casts. One is small and hard; the other two are softer, and one has several ramifications (original magnification $\times 2$).

Fig 5.—Bronchial casts in liquid medium. The larger one is concave.

Fig 6.—Bronchial cast. Low-power magnification of a histologic study. Several groups of squamous metaplastic cells can be seen within groups of lymphocytes (hematoxylin-eosin, original magnification $\times 100$).

Fig 7.—This is a middle-power magnification of cells from the same patient as in Fig 6. A group of squamous metaplastic cells is visible in the center with some leukocytes. Note the vacuolated appearance of the cells. This is a usual finding in squamous metaplastic cells (hematoxylin-eosin, original magnification $\times 400$).

Fig 8.—This is a high-power magnification of the cells in Fig 7. Note the appearance of the basal cells, some of which show vacuolation. A keratinized cell can be seen amid polymorphonuclear leukocytes (hematoxylin-eosin, original magnification $\times 800$).

Fig 9.—Histologic section. This is a fragment of a large bronchial cast. It consists of a great clump of polygonal clear cells, more or less vacuolated. On one side, coagulated fibrillar material is seen (hematoxylin-eosin, original magnification $\times 400$).

Table 2.—Biochemical Composition of Bronchial Casts

Component	% of Total Weight						Acute Catharral Bronchitis
	Cast Bronchitis by Patient No.						
	1	2	3	4	5	6	
Albumin	54.03	50.69	47.59	40.58	41.18	62.46	51.11

Fibrin	4.32	5.71	5.05	5.41	6.95	5.72	0.31
β_2 -Glycoprotein	0.86	1.36	1.60	1.08	1.60	1.17	5.72
IgG	13.39	12.53	16.31	18.93	17.96	7.49	14.05
IgA	10.15	10.36	9.63	11.48	11.47	7.67	9.79

ronchitis. On the other hand, the content of β_2 -glycoprotein in the bronchial exudate of patients with acute catarrhal bronchitis was more than threefold higher than in the casts.

Virus Isolation.—Results of all virus isolation studies were negative.

COMMENT

My study strongly suggests that a significant number of children classified as chesty child¹⁰ may be affected by an acute or chronic type of bronchitis characterized by the formation of bronchial casts. The diagnosis of cast bronchitis is made by examination of the bronchial secretions in the gastric fluid, since children less than 5 years old swallow the bronchial secretions, except in cases of bronchiectasis, pulmonary abscess, or whooping cough.

Eighteen of our patients had undergone extensive study for allergies and had a diagnosis of intrinsic asthma. Most of our patients with the chronic type of cast bronchitis are probably very similar, if not identical, to the 2.6% of cases reported by Labbe et al¹¹ of children with bronchiolitis who had chronic cough and functional signs of bronchial obstruction for an average period of observation of 18 months.

Many previous studies on obstructive

bronchitis (asthmatoïd or spastic bronchitis or bronchiolitis) have analyzed the clinical signs, radiologic findings, and hematologic and other laboratory measurements. A very recent study of 74 cases by Labbe et al¹¹ also included results of virologic studies in nasopharyngeal secretions and stools. Bronchial secretions were not studied.

Bronchial casts were composed mainly of metaplastic squamous epithelial cells. It is well known that physiologic desquamation of the upper gastrointestinal tract may result in the observation of isolated squamous epithelial cells in the gastric fluid.¹² In our series, however, the squamous epithelial cells were found to form cast structures, in many instances with evident ramifications. It is extremely unlikely that these structures originate on the surface of the planar pharyngeal or esophageal epithelium, since these surfaces are devoid of macroscopic anatomic invaginations.

The pathogenesis of cast bronchitis is unknown. Our initial hypothesis was that cast bronchitis might be secondary to a fibrinous type of inflammation as in diphtheria or pneumococcal infections (fibrinous cast bronchitis). The absence of a significantly greater amount of fibrin in the cast (fibrin content ranged between 4.32% and 6.99% [Table 2]) rel-

ative to blood plasma does not favor this hypothesis. The lower amount of β_2 -glycoprotein, less than 30% of that contained in the fluid exudate of acute catarrhal bronchitis, does not support the possibility that the mucous content may be a crucial factor in cast formation. On the other hand, histologic studies showing a direct relationship between the number of metaplastic cells and the strength of the casts very much favor the possibility that cast formation is mainly related to the cohesive forces that assemble the epithelial cells. The backbone of cast would be composed of clumps of epithelial cells with bridges among them and additionally held together by certain high-molecular-weight or coagulated proteins. The cast structure would be covered and would contain seromucous secretions.

Metaplastic transformation of the tracheobronchial epithelium is a well-described finding in adults, mainly secondary to chronic irritative stimulants such as tobacco smoke. Patients with asthma also have epithelial desquamation; however, their type of desquamation is completely different from that observed in patients with cast bronchitis. Sanerkin and Evans¹³ reported that the so-called creola bodies present in the bronchial exudate of patients with asth-

ma are mainly composed of epithelial cells of the typical bronchial epithelium (ciliated and mucinous cells) but not squamous epithelial cells, as found in the casts of the patients in our series.

There is little previous information on squamous metaplasia in the bronchial epithelium in childhood. In 1919, Askanazy¹⁴ reported squamous metaplasia in the tracheal and bronchial epithelium associated with viral infections ("metaplasierenden Katarrh") caused by influenza virus and some viral pneumonitis, such as measles pneumonia. The pathogenesis of squamous metaplasia remains to be determined. Nasiell¹⁵ suggested that it might be the result of a complex sequence of events starting with the disappearance of the cilia or with simple hyperactivity of the basal layer.

The etiology of cast bronchitis remains speculative. The clinical picture suggests the possibility of an allergic condition. However, in only one patient of our series could a type I hypersensitivity be proved. This patient had chronic cast bronchitis for 2 years. Subsequently, the skin tests for several al-

lergens were positive. At this writing the patient was 26 years old and had a history of chronic allergic asthma. The combination of increased serum IgE and eosinophilia in children with asthmatic bronchitis suggests extrinsic asthma.⁴ Elevation of both measurements was not found in the eight patients in whom determinations were made. Therefore, the absence of this finding in our patients with cast bronchitis suggests that an extrinsic allergic mechanism is not likely in the pathogenesis of the entity. The follow-up of at least 6 years in all cases confirms this impression. A relationship between cast bronchitis and cystic fibrosis is a second possibility. However, only one patient in our series had a positive sweat test and later developed the classic picture of cystic fibrosis.

The presence of fever, lymphocytosis, the age at onset (from 3 months to 5.5 years), the consistently negative routine bacteriologic analysis, the clinical course, and the lack of response to broad-spectrum antibiotics firmly support a viral cause. However, no viruses could be found in 11 bronchial

specimens.

Apart from wheezing, which was a common symptom in all of our patients, the population of patients described in this study is quite heterogeneous (intensity of symptoms, duration, etc). This heterogeneity suggests that squamous metaplasia of the bronchial epithelium may be a common and nonspecific finding in children with obstructive bronchitis. It may even occur in cases of obstructive bronchitis of less than 2 weeks' duration, which is very common in daily pediatric practice. Routine, careful examination of the gastric fluid is the only way to define the population of patients in whom these pathologic changes occur.

Although mainly descriptive, the findings in this report may constitute a basis for studies directed at better defining the pathophysiologic characteristics and etiology of obstructive bronchitis in infants and children.

We thank A. Corominas Vilardell, MD (Department of Biochemistry, Ciudad Sanitaria de Barcelona, Spain), for biochemical studies and A. Pumarola Busquets, MD (Department of Microbiology, University of Barcelona), for virologic studies.

Purpuric Rashes in Cystic Fibrosis

Daniel V. Schidlow, MD; Howard B. Panitch, MD; Nayere Zaeri, MD; Joseph Zenel, MD; Brad E. Alpert, MD

• Sixteen patients with cystic fibrosis experienced vasculitic rashes of the lower extremities that resembled hypergammaglobulinemic purpura. The rashes were associated with increased serum gammaglobulin G levels and rather severe lung disease. The rashes are probably the expression of chronic lung infection and high antigenic load in these patients. Their appearance was associated, in most cases, with poor long-term survival. (AJDC. 1989;143:1030-1032)

The appearance of vasculitic rashes, either alone or associated with non-specific arthritis, has been reported previously in a few patients with cystic fibrosis (CF).¹⁻³ The history and long-term implications of this manifestation, however, have not been reported. We present a series of patients with CF seen during a period of 10 years who experienced purpura of the lower extremities associated with increased serum gammaglobulin levels.

METHODS

We reviewed the records of patients with CF treated at St Christopher's Hospital for Children, Philadelphia, Pa, between 1977 and 1987. The diagnosis of CF had been made in all patients on the basis of a typical clinical picture and confirmed by the finding of increased concentrations of sweat electrolytes.

Patients were included in the series if they had a petechial or purpuric rash. We analyzed data obtained at the onset of the rash. These included age and pulmonary function test results as well as hematologic, immunologic, and available skin biopsy results.

The clinical, physical examination, and nutrition components of the original Shwach-

man-Kulczycki system⁴ were recorded. Roentgenograms were scored using the roentgenographic scoring system of Brasfield et al.⁵ Each individual received a maximum of 25 points for each of the four categories to a maximum of 100 points. Demerit points were subtracted to a minimum score of 5 points per category for maximum compromise. In patients who had died, survival after appearance of the rash was calculated.

RESULTS

Sixteen of approximately 500 patients with CF seen from 1977 to 1987 experienced purpura of the legs and feet. The group comprised 8 male and 8 female patients. All patients had *Pseudomonas* species in their respiratory secretions and were being treated with antibiotics, chest physical therapy, and aerosolized mucolytic or bronchodilator drugs. Fourteen patients (78%) were receiving pancreatic enzymes.

The mean age at onset of the rash was 20 years 3 months (range, 9 years 8 months to 33 years 5 months). The mean score at the time the rash was present was 55 (range, 30 to 78). Pulmonary function measurements were abnormal in all patients and ranged in severity from moderately obstructive to severely obstructive-restrictive patterns.

Raised, palpable petechial lesions appeared below the knee and were most prominent over the dorsa of the feet, ankles, and tibial surfaces (Fig 1). In three patients the rash was also present on the soles of the feet. The rash appeared suddenly, frequently associated with pruritus and a burning sensation and slight edema of the feet. It faded spontaneously in 3 to 7 days. The eruption seemed to follow prolonged standing and use of tight garments, such as socks or leather straps of ladies' shoes. Cold temperature did not bring on or affect the rash.

Patients were occasionally treated with nonsteroidal anti-inflammatory

and antihistaminic drugs to relieve pain and pruritus. This therapy did not appear to modify the duration of the rash or its intensity. Corticosteroids were not used. All but four patients experienced multiple recurrences and, eventually, a diffuse purple-brown pigmentation of the affected areas developed (presumably from repeated extravasation of blood into the skin). Five patients (28%) had concomitant arthritis at the onset of the rash. One individual had acute manifestations of hypertrophic osteoarthropathy, with knee and ankle effusions and periosteal elevation.

In six patients (38%) a skin biopsy specimen was obtained. Microscopic examination of the lesion (Fig 2) showed a variable degree of vasculitis and perivascular infiltrate involving mainly the capillaries and venules of the papillary dermis. No immunoglobulin deposits were detected in the three cases in which immunofluorescence techniques were used.

The mean white blood cell count was $10.9 \times 10^9/L$ (range, $5.8 \times 10^9/L$ to $19.3 \times 10^9/L$). Leukocytosis was present only in those patients who had pulmonary exacerbations at the time of the eruption. Slight eosinophilia was seen in three individuals (the absolute eosinophil count was between $400 \times 10^6/L$ and $600 \times 10^6/L$). None of the patients was anemic or leukopenic, with the exception of one patient with cirrhosis of the liver, hypersplenism, and repeated variceal bleeding. Excluding this patient, the mean hemoglobin count was 130 g/L (range, 120 to 169 g/L).

In all 12 patients who had quantitative immunoglobulin determinations, IgG was increased beyond the upper limits of the normal range for age (Table). Immunoglobulin A was elevated in 4 patients (33%), and IgM was elevated in 2 patients (16%). Immunoglobulin E levels were normal in all 12 individuals.

Accepted for publication January 11, 1989.

Fig 1.—Purpuric rash of the lower extremity in a patient with cystic fibrosis.

Fig 2.—Skin biopsy specimen of purpuric rash in a patient with cystic fibrosis. Endothelial swelling (arrow) and mixed inflammatory infiltrate within and around small blood vessels is seen in the dermis. There is also focal damage of vessel walls (hematoxylin-eosin, original magnification $\times 100$).

Five (71%) of 7 patients tested had circulating immune complexes (by C1q binding), but none had decreased complement levels.

The diagnosis of Schönlein-Henoch purpura was initially made in one patient based on a mild, transient elevation of the serum urea nitrogen and creatinine concentrations. Results of urinalysis and kidney biopsy were suggestive of this condition. After the renal involvement subsided, the rash recurred several times. All other patients had normal renal function and urine sediment. No patient was hyperuricemic.

At the time of this report, 13 (81%) of the 16 patients had died. The median survival after the appearance of the rash was 16 months (range, 2 to 59 months). The mean and median ages at death were the same: 23 years 3 months

(range, 12 years 5 months to 36 years 1 month).

COMMENT

The characteristics of the skin eruption in our patients with CF are similar to those of hypergammaglobulinemic purpura. This entity was first described by Waldenström⁶ in 1943 and was later reported in four patients with CF by Nielsen et al.⁷ Typically, patients with hypergammaglobulinemic purpura experience recurrent purpuric spots in the lower extremities along with pruritus and a burning sensation in the affected areas. The rash and symptoms are frequently brought on by prolonged orthostatic position. Permanent pigmentation of the skin and polyclonal elevation of circulating gammaglobulins, especially of the G fraction, are also charac-

teristic of this condition. Treatment with anti-inflammatory drugs does not seem to affect the clinical course of hypergammaglobulinemic purpura.⁶

The differential diagnosis includes Schönlein-Henoch purpura; some authors have suggested that Schönlein-Henoch purpura and hypergammaglobulinemic purpura are extremes of the same clinical spectrum, a hitherto unproved hypothesis.⁶ Unlike Schönlein-Henoch purpura, however, hypergammaglobulinemic purpura tends to recur numerous times and can develop in association with collagen vascular diseases.⁶ Purpura, arthritis, and kidney disease have also been described in celiac disease,⁸ bowel-associated dermatosis-arthritis syndrome,⁹ and chronic pulmonary disease¹⁰ with humoral and tissue evidence of immune-mediated damage.

Quantitative Immunoglobulin Levels in Patients With Cystic Fibrosis With Purpuric Rashes

*Value was greater than the normal range for age in our laboratory.

†Circulating immune complexes were present.

‡The patient was still alive at the time of this report.

It is unlikely that this rash represents a drug reaction. We found no temporal relationship between the administration of specific drugs (such as penicillins) and the onset of purpura. In the absence of specific testing, however, drug hypersensitivity cannot be ruled out with certainty.

Soter et al¹ have previously characterized vasculitic rashes in patients with CF as cutaneous venulitis. Their patients and ours had very similar clinical and laboratory findings.

An exaggerated immune response against bacterial antigens has been

postulated as an important factor in the pathogenesis of tissue damage and inflammation in CF.¹¹ In general, patients with CF with hypergammaglobulinemia have more severe lung involvement and a poorer prognosis than those with normal or low levels of gamma globulin.^{11,12}

The low incidence of purpura in this series is difficult to explain, given the large population of severely ill patients with CF with hypergammaglobulinemia. We were not able to define specific factors that made our patients conspicuously different from similarly ill pa-

tients. A long-term surveillance study would be needed to explore this issue.

In summary, the onset of purpuric rashes of the legs and feet is probably a secondary manifestation of the severity of lung disease in CF. In most patients it is associated with poor long-term survival; thus, it heralds a poor prognosis.

This study was partially funded by a center grant from the Cystic Fibrosis Foundation and by a demonstration grant (SPRANS MCJ-423525) from the Bureau of Maternal and Child Health, US Department of Health and Human Services, Rockville, Md.

Dr Panitch was a Cystic Fibrosis Foundation fellow while conducting this study.

Emergence of Isolates Resistant to Ampicillin

David G. Rupar, MD; Margaret C. Fisher, MD; Hansel Fletcher, MS; Joel Mortensen, PhD

• Clinical isolates of *Streptococcus faecium* demonstrating ampicillin resistance were recovered from eight pediatric patients. Sites of isolation included blood, surgical wound, bile drainage, urine, burns, and peritoneal fluid. Seven patients had prolonged hospitalization, and all had been treated with broad-spectrum antibiotics prior to isolation of the resistant enterococcus. One isolate was from an ill, bacteremic patient; the others were in mixed culture and were not considered causes of disease. The isolates were not epidemiologically related. Minimal inhibitory concentrations for various antibiotics included ampicillin (16 to 32 mg/L), penicillin (128 mg/L), gentamicin (16 mg/L), and vancomycin (2 mg/L). Three isolates demonstrated high-level resistance (>2000 mg/L) to streptomycin; none did so to gentamicin. In vitro synergy testing performed on seven available isolates for ampicillin and gentamicin demonstrated no synergy to this combination. None produced β -lactamase. Combined antibiogram and plasmid data showed at least five distinct patterns. These strains present a new clinical problem in their high level of resistance to ampicillin and to the combination of ampicillin and gentamicin. (AJDC. 1989;143:1033-1037)

Enterococci are constituents of normal bowel flora and are important causes of nosocomial infections. The incidence of nosocomial infections due to enterococci is increasing.¹ Enterococci account for approximately 10% of endemic hospital-acquired infections,^{2,3} making them the third most common cause of nosocomial infections. Occasionally, enterococci cause epidemics in

the hospital setting.^{4,5} Two species, *Streptococcus faecalis* and *Streptococcus faecium*, are primarily responsible for human disease; of these, *S. faecalis* is by far the more common.⁶

Enterococci are generally considered to be of low pathogenic potential, yet many types of infection, including endocarditis, urinary tract infection, and surgical and burn wound infection, are caused by enterococci. Polymicrobial infections are common.^{7,8} Bacteremia results from a focal infection or arises spontaneously, and is attended by significant morbidity and mortality.⁹ In pediatrics, enterococci have achieved prominence as a cause of neonatal septicemia and meningitis.^{5,10,11} Hemming et al¹² reported that enterococci were the second most common cause of nosocomial bacteremia in the neonatal intensive care unit, occurring less commonly than *Escherichia coli* but with equal frequency as *Staphylococcus aureus*. At our institution, enterococcal infection accounts for 7% of nosocomial bacteremia and is frequently related to the use of intravascular catheters.¹³

Between December 1986 and March 1988, eight enterococcal isolates exhibiting an unusual degree of ampicillin resistance were identified by the Clinical Microbiology Laboratory at St Christopher's Hospital for Children, Philadelphia, Pa. The organisms were studied further to define susceptibilities, plasmid patterns, and presence of β -lactamase. Medical records of the patients colonized by these strains were reviewed.

METHODS

Organisms were identified as enterococci by growth on 4% bile and 6% sodium chloride and by esculin hydrolysis. Speciation was performed by a commercially available identification system (Rapid Strep, API Analytab Products, Plainview, NY). Standard disk diffusion susceptibility testing was performed on each isolate. Strains displaying an

absence of any zone of inhibition around a 10- μ g disk of ampicillin were studied further. Minimal inhibitory concentration (MIC) was measured by a commercial antibiotic sensitivity system (American Micro Scan, Baxter Healthcare Corporation, Edison, NJ).

Seven of eight strains were available for further study. American Type Culture Collection strain 29212 (*S. faecalis*) was used as a control in all experiments. Minimal inhibitory concentrations for ampicillin and gentamicin were determined by the broth microdilution method, using serial two-fold dilution of the antimicrobial agent in Mueller-Hinton broth (Difco Laboratories, Detroit, Mich). The MIC was defined as the lowest concentration of the agent at which there was no visible growth after 18 hours' incubation at 37°C. Synergy between ampicillin and gentamicin was determined by the checkerboard microdilution method.¹⁴ The range of final ampicillin concentrations was 0.25 to 128 mg/L, and that of gentamicin was 0.5 to 32 mg/L. Each well was inoculated with organisms to give turbidity equivalent to a final concentration of 5×10^5 organisms per milliliter. The fractional inhibitory concentration (FIC) index was defined as (MIC A combined/MIC A alone) + (MIC B combined/MIC B alone), where MIC A and MIC B represent MICs for the two antibiotics, each measured alone and combined with the other.

Synergy was considered present when the FIC index was less than or equal to 0.5. β -Lactamase activity was tested using nitrocefin disks (Cefinase, BBL Microbiology Systems, Cockeysville, Md) and a plate acidometric method. Cultures were tested in both stationary and logarithmic phases of growth.

Whole-cell DNA was isolated and characterized by standard methods.¹⁵ Briefly, cell lysates were treated with sodium dodecyl sulfate and the DNA was spooled onto a glass rod. Solutions of DNA were electrophoresed on a horizontal gel apparatus (Model HE 99, Hoefer Scientific Instruments, San Francisco, Calif) in a 0.7% agarose gel and stained with ethidium bromide solution.

Patient information was obtained by review of medical records. Epidemiologic data obtained included dates of hospitalization, nursing unit and room, attending physician, resident physician, consulting physicians,

Accepted for publication March 29, 1989.

From the Departments of Pediatrics and Laboratory Medicine, St Christopher's Hospital for Children (Drs Rupar, Fisher, and Mortensen); and the Department of Microbiology and Immunology, Temple University School of Medicine (Mr Fletcher), Philadelphia, Pa. ancillary hospital services used, surgical procedures, and antimicrobials administered.

RESULTS

Patient information is summarized in Table 1. Ampicillin-resistant enterococci (ARE) were cultured from seven patients between December 1986 and December 1987; the blood isolate was obtained in March 1988. Patients were not related by date of hospitalization, room number, nursing unit, physician caregivers, or ancillary hospital services utilized (ie, respiratory care, physical therapy, etc).

Patients 1 through 7 had serious underlying diseases that placed them at risk for nosocomial infection. Patient 2 was receiving immunosuppressive therapy. Patients 1, 2, 5, 6, and 7 were in the hospital a mean of 14 days (range, 8 to 30 days) preceding the isolation of ARE. Patients 3 and 4 had been readmitted after recent prolonged hospitalizations. These seven patients had received multiple courses of antibiotics in the month prior to isolation of ARE. All were treated with β -lactams, including ampicillin sodium (n=4), nafcillin sodium (n=2), methicillin sodium (n=1), and third-generation cephalosporins (n=3). Six had received an aminoglycoside antibiotic, either gentamicin sulfate or tobramycin sulfate. These seven pa-

tients, although chronically ill, did not show evidence of acute infectious illness. Only three of the patients were febrile, and two of these had alternate explanations for the fever. Specimens from patients 2, 4, 5, and 7 were obtained from superficial sites. These were taken as "surveillance" cultures from patients with minimal erythema or drainage but no evidence of cellulitis or "wound sepsis." The isolate from pa-

tient 1, a child with bilateral ureterostomies, was recovered from a urine sample obtained as follow-up after a urinary tract infection. The colony count was less than 100 colony-forming units/mL and urinalysis was unremarkable. The ARE isolate from patient 6 was obtained from a culture of ascitic fluid obtained at the time of splenectomy; the patient did not have peritonitis. The remaining isolate was obtained from aspi-

rate of an area of cellulitis. None of these seven patients received specific therapy for the enterococcal isolate. Patient 6 died 2 days after ARE was recovered; infection was not the major cause of death.

Patient 8 was a 3-week-old neonate who was hospitalized because of fever, irritability, and an infected scalp wound. This neonate had received 2 days of therapy with ampicillin and gentamicin in the first week of life because of fever. No focus of infection was detected, antibiotics were discontinued, and he was discharged in apparently good health. On rehospitalization, he was treated with ampicillin, gentamicin, and vancomycin hydrochloride, and he improved rapidly. Enterococci were recovered from blood obtained at the time of admission. Ampicillin and gentamicin were discontinued, and vancomycin

therapy was given for 10 days.

All ARE isolates were identified as *S faecium*. The blood isolate was a pure culture; all others were found in mixed culture. Associated organisms isolated included coagulase-negative staphylococci, *Pseudomonas aeruginosa*, *Klebsiella oxytoca*, *E coli*, and yeast.

Antibiotic susceptibility data are shown in Table 2. Isolates in patients 1 through 5 and 7 each demonstrated an ampicillin MIC of 32 mg/L; the isolate in patient 8 had an MIC of 16 mg/L. The one strain that was not available for further testing (from patient 6) had an ampicillin MIC of greater than 16 mg/L but less than or equal to 128 mg/L on the commercial MIC panel. No isolate produced detectable β -lactamase. Three isolates demonstrated high-level resistance to streptomycin, but none did so to gentamicin. Comparison of antibiotic

susceptibilities to streptomycin and tetracycline showed three distinct antibiograms. Despite the lack of high-level resistance to gentamicin, all strains had FIC indexes of at least 2.0, indicating no synergy between ampicillin and gentamicin. The control strain, by contrast, had an FIC index of 0.25. Strains from patients 7 and 8 had FIC indexes of greater than 2.0, suggesting antibiotic antagonism.

A review of 75 random isolates of enterococci obtained before the appearance of the ARE at St Christopher's Hospital for Children showed none to be resistant to ampicillin by disk diffusion susceptibility testing.

Plasmid preparations are shown in the Figure. All strains demonstrate a large plasmid (>20 kilobase pairs). The strain from patient 1 (lane A) shows a small plasmid not present in the other strains. A restriction endonuclease, Hind III, digest of the DNA of the strains (lanes A' to G') shows a 1.8-kilobase fragment present only in the strain from patient 1 (lane A'). Strains from patients 2, 3, 5, 7, and 8 (lanes B', C', E', F', and G') show a similar Hind III profile. When all the isolates were probed with a tetracycline-resistant determinant from the transposon Tn916, only the large plasmid of strain from patient 4 (lane D) was homologous (H.F., Laura Marri, MS, Lolita Daneo-Moore, PhD, unpublished data, 1988). Thus, by plasmid analysis there are at least three groups. By analysis of antibiogram (Table 2), strains from patients 2, 3, 5, 7, and 8 have at least three different susceptibility patterns. Therefore, there are at least five different strains represented.

COMMENT

We describe the emergence of high-level resistance to ampicillin in strains of enterococci recovered from eight patients at St Christopher's Hospital for Children. These clinical isolates of *S faecium* have MICs for ampicillin above the published range for this organism. Furthermore, no in vitro synergy of ampicillin and gentamicin could be demonstrated against these strains despite the lack of high-level resistance to gentamicin. The mechanisms for this are not established; preliminary observations

Agarose gel electrophoresis of cellular DNA isolated from clinical isolates of *Streptococcus faecium*. Lanes A through G are isolates from patients 1, 2, 3, 4, 5, 7, and 8. Lanes A' through G' are Hind III digested DNA from the same patients. kb indicates kilobase.

upport the theory that resistance results from alterations in the organisms' penicillin-binding proteins (H.F. and Lolita Daneo-Moore, PhD, unpublished data, 1988). This is consistent with the laboratory observation that gradual increases in antibiotic pressure allow the development of penicillin-resistant enterococci associated with changes in the penicillin-binding protein profile.¹⁶ These isolates were not related epidemiologically. All our patients were at risk for nosocomial infections due to prolonged hospital stay and use of multiple antibiotics. The use of third-generation cephalosporins and aminoglycosides has been associated with enterococcal infections, including those due to high-level aminoglycoside-resistant strains.^{17,18}

The pattern of plasmids suggests that these are several different strains. Antibigrams also varied. This unrelatedness was surprising; we expected to find nosocomial transmission of a single strain with an unusual level of ampicillin resistance. It is likely that each patient acquired the infective strain from his or her own bowel flora, rather than from other patients or hospital personnel.

In the first seven patients, the organisms did not cause infection. The appearance of the bacteremic patient confirmed the potential clinical importance of these organisms. Enterococci have significant pathogenic potential and are major causes of nosocomial infection. *Streptococcus faecium* in particular has been reported as a cause of serious hospital outbreaks of infection in infants.⁵

Enterococci are resistant to a wide variety of antibiotics: cephalosporins of all generations, aminoglycosides, clindamycin, trimethoprim-sulfamethoxazole,

erythromycin, and tetracycline.⁶ Resistance may be intrinsic or acquired via plasmids.¹⁹ The most active agents against enterococci are ampicillin and vancomycin. Even for these, however, enterococci display relative resistance compared with other streptococci. The concentration of ampicillin needed to inhibit 90% of enterococcal strains (MIC₉₀) in published studies is 1 mg/L (range, 0.25 to 4 mg/L),⁶ while the MIC for other streptococci is usually less than 0.1 mg/L. Minimum inhibitory concentrations of penicillin are usually twofold to fourfold higher than those of ampicillin. *Streptococcus faecium* appears to be the more resistant species, with an ampicillin MIC₉₀ of 2 mg/L, and a range from 0.12 to 16 mg/L.²⁰ The mechanism for this "relative resistance" to penicillin and ampicillin in enterococci appears to be the existence of low-affinity penicillin-binding proteins in the cell wall.²¹ Production of β -lactamase, a common bacterial means for penicillin resistance, has not been common among enterococci, though several β -lactamase-producing strains have been reported.²² In general, the susceptibility to penicillins of enterococci has remained stable through the years, with no significant increase noted.^{1,6}

Enterococci demonstrate tolerance to the bactericidal effect of antibiotics acting on the cell wall.^{23,24} Successful therapy of serious enterococcal infections has depended on use of two antibiotics that act synergistically to kill the organism.²⁵⁻²⁷ Aminoglycoside antibiotics, though not active against enterococci at clinically achievable, safe levels, have been found to act in concert with penicillin, ampicillin, or vancomycin to kill the organisms at usual therapeutic

doses.²⁸⁻³⁰ These laboratory observations have been supported by data on experimental endocarditis in animals,³¹ and more importantly by the historical observation that patients with enterococcal endocarditis fared much better when given a combination therapy than a single-agent treatment.³²⁻³³ The strains described in this report do not demonstrate synergy of ampicillin and gentamicin. The child with bacteremia and an infected scalp wound recovered after local drainage of the wound and parenteral therapy with vancomycin.

Vancomycin is the drug of choice for serious enterococcal infections in patients allergic to penicillin. Vancomycin is not bactericidal for enterococci at therapeutic concentrations but does act synergistically with aminoglycosides to kill the organisms.^{29,34} All the isolates in this series were sensitive to vancomycin. However, vancomycin resistance in enterococci has recently been described.^{35,36}

The findings in eight patients colonized by resistant enterococci during a 15-month interval emphasize the importance of routine antibiotic susceptibility testing of all enterococcal isolates. These strains provide yet another example of the ability of microorganisms to adapt to their environment and thwart attempts by modern medical science to combat them. The emergence of ampicillin resistance among enterococci is almost certainly a result of extensive use of antibiotics. The overuse of antibiotics sets the stage for their obsolescence and replacement by more exotic, expensive, and potentially toxic agents.

The authors thank Lolita Daneo-Moore, PhD, for her guidance and advice, and Laura Marri, MS, for her technical assistance.

Book Review

Migraine in Childhood, edited by Judith M. Hockaday, 158 pp, \$29.95, Butterworth Publishers Inc, Stoneham, Mass, 1988.

Migraine in Childhood, edited by Judith M. Hockaday, MD, of the John Radcliffe Hospital in Oxford, England, is clearly written and clinically useful. The monograph is brief but complete, well organized, and logically presented. The tightness and clarity of the text completely make up for the lack of illustrative figures and the presence of only a few tables. The book reads well, and the work of all eight contributors is skillfully edited and well referenced. It is a welcome addition to the literature on migraine in children.

Dr Hockaday provides a clinically useful definition of migraine, stressing positive criteria, exclusion of other causes, and a mandatory follow-up period. Clinical features and variants are well discussed, with full consideration given to diagnostic limitations. However, the recommendations concerning neuroimaging are vague. The reader is warned not to delay diagnosis of brain tumors and to consider other intracranial and extracranial causes of headache. However, more specific guidelines for computed tomography or magnetic resonance imaging would be helpful.

The neurologic features of migraine are addressed more thoroughly than the gastrointestinal issues. Dr Hockaday clearly points out the difficulties in assigning a diagnosis of abdominal migraine, and provides a useful clinical approach to the problem. However, psychosomatic factors are strongly emphasized as a cause for recurrent abdominal

pain in children, and the differential diagnosis is focused on rarities, such as urea cycle disorders and mitochondrial cytopathy. Guidelines are lacking for consideration of more common causes, such as gastroesophageal reflux, lactose intolerance, constipation, infection with parasites (such as *Giardia lamblia*), or structural abnormalities.

Sensible and helpful advice is provided for the symptomatic treatment of migraine attacks, although one might disagree with the emphasis on metoclopramide as the antiemetic because of its frequent neurologic side effects. In addition, prophylactic treatment for children with frequent, severe attacks is deemphasized to the extent that few specific recommendations are provided. Finally, it should be noted that the recommended dosage of cyproheptadine (30 mg twice daily) is considered high by American standards. For example, the *1989 Physicians' Desk Reference* states that the dosage should not exceed 12 mg/d for children 2 to 6 years of age or 16 mg/d for children 7 to 14 years of age.

Dr Hockaday et al have provided children's physicians with a worthwhile volume on migraine. I agree with the authors that the problem is more common than most doctors realize. Their monograph may help close that gap.

Anti-*Staphylococcus aureus* IgE Antibodies for Diagnosis of Hyperimmunoglobulinemia E-Recurrent Infection Syndrome in Infancy

Aubert Lavoie, MD; Menachem Rottem, MD; Marshall P. Grodofsky, MD; Steven D. Douglas, MD

• Four infants with hyperimmunoglobulinemia E presented with a persistent papulovesicular rash and eosinophilia. Serum IgE levels and specific anti-*Staphylococcus aureus* IgE antibodies were studied during the first year of life. Increased anti-*S aureus* IgE antibodies were an early indicator of the disease; they appeared as soon as 7 weeks of age in patient 1 and before 1 year of age for the other patients. These antibodies were detected before the development of deeper staphylococcal infections. Prompt diagnosis and treatment are important, as they may prevent long-term infectious complications.

(AJDC. 1989;143:1038-1041)

The hyperimmunoglobulinemia E-recurrent infection syndrome (HIE) is a rare disorder characterized by recurrent severe infections of the skin and sinopulmonary tract, including staphylococcal pneumonias with pneumatocele formation, chronic eczematoid dermatitis, coarse facial features, mild eosinophilia, and markedly elevated serum IgE levels.^{1,2} Although the primary defect is still unknown, a number of immunologic abnormalities have been identified, including the presence of specific antimicrobial IgE antibodies directed against *Staphylococcus aureus* and *Candida albicans*,^{3,4} deficits of salivary total IgA and anti-*S aureus* IgA,⁵ a neutrophil chemotactic defect,^{2,6,7} an abnormal T-cell number and function,⁸ and

impaired antibody responses to carbohydrate and protein antigens.⁹ Our laboratory has developed an assay for IgE antistaphylococcal antibodies that has become a diagnostic test.³ The disease has its onset in infancy, usually within the first 3 months of life.^{2,10,11} Recognition of the syndrome, however, may be difficult in the newborn period, because the clinical features and laboratory studies in the infant have not been well delineated.

We describe four infants who, during the first 2 months of life, had a persistent papulovesicular skin rash, marked eosinophilia, and anemia. The HIE was confirmed when they developed *S aureus* infection, very high levels of serum IgE, and anti-*S aureus* IgE antibodies.

PATIENT REPORTS

PATIENT 1.—A white male neonate was the 4.35-kg product of a 43-week gestation born to a 23-year-old primigravida. Two days after birth, he developed a vesicular rash on the hands and feet. Although Tzanck smears and bacterial and viral cultures from mother and neonate were negative, he received acyclovir and antibiotics for a presumed herpes infection. The only unusual laboratory findings were significant eosinophilia (0.16 of a total leukocyte count of $29.7 \times 10^9/L$) and a hemoglobin level of 109 g/L.

At 7 weeks of age he was hospitalized with fever; his rash had become more diffuse, weeping, and crusted, involving the trunk and scalp. Hepatosplenomegaly and purulent otitis externa were also noted. A skin biopsy revealed a diffuse eosinophilic infiltration of the epidermis with intraepidermal vesicles. Laboratory data are shown in Table 1. Culture from skin lesions yielded *S aureus*, *Enterobacter cloacae*, *Escherichia coli*, and *Klebsiella oxytoca*. Complement level was normal ($CH_{50} = 114$ hemolytic units/mL).

At 8 months of age he was hospitalized for a

S aureus axillary adenitis and treated with surgical drainage and oxacillin. Immunologic tests revealed elevated serum levels of IgE (235 $\mu g/L$ [normal, 0 to 36.5 $\mu g/L$]) and IgG (10.00 g/L [normal, 2.92 to 8.16 g/L]), with normal levels of IgM (1.16 g/L [normal, 0.37 to 1.24 g/L]) and IgA (0.41 g/L [normal, 0.27 to 0.73 g/L]); isohemagglutinins were anti-B 1:32 (blood group A+); and there was delayed neutrophil killing of *S aureus*, with reduced random migration and chemotaxis toward formyl-methionyl-leucyl-phenylalanine relative to control. Nitroblue tetrazolium test results were normal. T-cell subsets (CD3, CD4, CD8) as well as mitogen responses (phytohemagglutinin, concanavalin A, pokeweed mitogen) were normal. Eosinophilia persisted (0.21 eosinophils of a leukocyte count of $18.4 \times 10^9/L$).

At 11 months of age he presented with an *S aureus* right middle- and lower-lobe pneumonia and pleural effusion. Despite intravenous oxacillin therapy, he developed a pneumatocele and a pneumothorax. His IgE levels were above 24 000 $\mu g/L$. Specific antistaphylococcal IgE antibodies were elevated in serum from 7 weeks of age, with 32% binding (normal, <10% binding) and at 8 months of age, with 52.6% binding.

During the following years he continued to have chronic skin infections, repeated otitis media, adenitis, and a pulmonary abscess. Serial values of serum IgE levels and anti-*S aureus* IgE antibodies are shown in Table 2; eosinophil count remained mildly elevated (0.06 of a leukocyte count of $6.2 \times 10^9/L$). He was treated with daily dicloxacillin.

The following two patients are sisters born to a black mother having classic HIE who also has had a brother and a sister afflicted with the same disorder. They have had a typical course of disease, characterized by recurrent staphylococcal pneumonias, some with pneumatocele formation, abscesses, dermatitis, nail changes due to *C albicans* infection, and IgE levels greater than 5000 $\mu g/L$. Specific anti-*S aureus* IgE antibodies were elevated in the mother (18.7% binding) and in the mother's brother (27.1% binding).

Accepted for publication May 2, 1989.

From the Department of Pediatrics, Division of Allergy-Immunology-Bone Marrow Transplantation, Children's Hospital of Philadelphia, University of Pennsylvania Medical School. Dr Lavoie is now with Unité de recherche, Inflammation et Immunologie-Rhumatologie, Centre Hospitalier de l'Université Laval. Dr Grodofsky is now with Pediatric Allergy Associates, Hartford, Conn.

Chemotaxis	Decreased	Decreased	Normal	...

PATIENT 2.—A black female neonate was the 3.4-kg product of a full-term pregnancy of a 21-year-old woman. At 3 weeks of age she had an upper respiratory tract infection and fever. She was hospitalized and treated with antibiotics despite negative cultures. She had papular and pustular skin lesions over her face (Figure) and a diaper rash. Complete blood cell count revealed a leukocyte count of $27.3 \times 10^9/L$, with 0.15 eosinophils and a hemoglobin level of 127 g/L.

At 6 weeks of age the skin rash had spread to her face, scalp, ears, and back and was oozing and crusted. Coughing persisted with yellowish sputum production. On physical examination, her weight was 3.58 kg (10th percentile) and her height was 54.5 cm (25th percentile). There was evidence of bilateral external otitis; no lymphadenopathy or abscesses were found. Laboratory studies are summarized in Table 1. The chest roentgenogram was normal. She was administered dicloxacillin and gained 0.7 kg over the following week, with significant improvement of her skin rash. Oral candidiasis developed, which was treated with nystatin (Mycostatin). The laboratory studies at 3 months of age revealed a persistent eosinophilia (0.44 of a leukocyte count of $31.5 \times 10^9/L$) with a hemoglobin level of 98 g/L.

At 6 months of age she manifested increased pruritic papulovesicular rash over her face, head, and upper portion of the chest. Her weight was 6.58 kg (25th percentile). She had bilateral otitis and two enlarged cervical nodes. Onychodystrophic changes of the left index finger were noted

and cultures yielded *C albicans*. Neutrophil chemotaxis toward formyl-methionyl-leucyl-phenylalanine and random migration were both markedly decreased. T-cell subsets were CD3, 62% binding (control, 81%); CD4, 44% binding (control, 47%); CD8, 8% binding (control, 27%); and a CD4 to CD8 ratio was 3.4 (control, 1.7). The mitogen responses were normal. Culture of scalp lesions yielded *S aureus* coagulase positive at 40%, as well as group D streptococcus, *Citrobacter*, *Streptococcus pneumoniae*, and *S aureus* coagulase negative. Serial studies of serum IgE levels and anti-*S aureus* IgE antibodies are presented in Table 2. She was treated with prophylactic dicloxacillin.

PATIENT 3.—A black female neonate was the 2.95-kg product of a 22-year-old woman. The pregnancy was complicated by a septic hip joint of the mother during the third trimester. Soon after birth the neonate had pustular lesions on her face. A sepsis workup showed no evidence of infection. One week later, while receiving intravenous antibiotic treatment, the facial eruption worsened and a diaper rash appeared; *S aureus* coagulase positive grew from a small pustule of her skin. Acute otitis media developed, which required a more aggressive antibiotic treatment. Prophylactic oral antistaphylococcal antibiotic therapy was continued.

At the age of 4 months, her weight was 4.5 kg (<5th percentile), her height was 58.5 cm (10th percentile), and her head circumference was 41 cm (51st percentile). The skin was remarkable for an excoriating papular erythematous rash on her face, upper torso,

*The normal range is 1 to 24 $\mu g/L$.

†The normal binding is less than 10%.

Patient 2. The appearance of facial papular and pustular lesions.

and diaper area. She also had dull tympanic membrane of her right ear and enlarged cervical lymph nodes. Laboratory studies are shown in Table 1. Circulating T- and B-cell numbers were normal.

During the ensuing months the course of her disease was characterized by recurrent otitis media and chronic skin eruption superinfected with *S aureus* and *C albicans*. Ther-

apy consisted of continuous antibiotics and topical treatment. Eosinophil count at 11 months of age was 0.16 of a leukocyte count of $20.2 \times 10^9/L$. Serial serum IgE levels and anti-*S aureus* IgE antibodies are summarized in Table 2.

PATIENT 4.—A white male neonate was the 3.3-kg product of a full-term pregnancy of a 20-year-old primigravida. Since birth he had a chronic papular rash on his face. He developed an eczematous dermatitis in the diaper area resistant to topical antifungal and corticosteroid therapy. In addition, he had recurrent bilateral external otitis. Laboratory findings at 1 year of age are shown in Table 1.

At the age of 18 months, physical examination showed height and weight in the 75th and 95th percentiles, respectively, for his age. He had bilateral purulent discharge from both ears, oral thrush, diffuse erythematous papular rash with excoriations over his face, neck, chest, back, and diaper area, and mild lymphadenopathy.

Serial studies of serum IgE levels and anti-*S aureus* IgE antibodies are shown in Table 2. Complement level was normal (CH_{50} = 110 hemolytic units). Skin tests for delayed-type hypersensitivity (performed toward tetanus, mumps, purified protein derivative, *C albicans*, and trichophyton) showed no reaction. Nitroblue tetrazolium test results were normal; chemotaxis was normal; isohemagglutinins were anti-A 1:32 (blood group B +). Skin biopsy taken from an affected lesion of the chest showed focal infiltrates of histiocytes and eosinophils of the dermis, with extension to the dermal-epidermal interface preserving the epidermis; electron microscopy showed no evidence of Birbeck granules of the Langerhans cell type. Bone survey findings were normal. Sinus films revealed diffuse opacification of the maxillary, ethmoid, and sphenoid sinuses. Chest roentgenogram showed infiltrates in right middle lobe and the adjacent medial basilar segment of right lower lobe. He was treated for his sinusitis and pneumonia. He later developed skin abscesses and recurrent sinusitis, although generally his skin condition improved by local hygiene and long-term use of antibiotics.

COMMENT

We have described four infants who demonstrated the characteristics of HIE: recurrent *S aureus* infections with a predisposition for pneumonia and pneumatocele formation, subcutaneous abscesses, chronic dermatitis, external otitis, adenitis, markedly elevated IgE levels, and eosinophilia.^{2,10,11} All infants manifested an early onset and persistent papulovesicular rash associated

with an exaggerated eosinophilia. Subsequently, they developed typical bacterial infections and markedly increased serum IgE levels. Although the disease develops in early infancy and the clinical features have been previously reported,¹¹ in most of the cases the diagnosis is delayed until childhood. The incomplete clinical picture for infants makes diagnosis difficult. Furthermore, the laboratory findings, including serum IgE levels and anti-*S aureus* IgE antibodies, have not been well studied in young infants; our patients are informative in that respect.

Chronic pruritic dermatitis is a very common manifestation of the syndrome.^{2,10} It is often referred to as an eczematoid rash. In our patients, the skin rash was their first clinical manifestation of the disease and started shortly after birth. Buckley and Sampson,¹¹ in a review of 21 patients, noted that most of their patients had a "history of pruritic dermatitis earlier in life." Similar clinical findings have been mentioned in other articles where the disease was recognized later during childhood.¹²⁻¹⁵ In our infants, the rash consisted of ill-defined papular and pruritic lesions with small superficial pustules and occasionally of superimposed crusted, infected plaques. It involved mainly the face, scalp, neck, and upper portion of the chest. The presence and severity of the dermatitis has recently been associated with elevated urinary histamine, degree of eosinophilia, and antistaphylococcal IgE antibodies.¹⁶

The second noticeable feature of these infants is the striking level of eosinophilia. Peripheral blood eosinophils are known to be decreased at birth and during the immediate postnatal period.¹⁷ The normal eosinophil count in children is approximately $0.24 \times 10^9/L$ (range, 0 to $0.74 \times 10^9/L$).¹⁸ In our fourth patient and in a review of 13 patients with HIE,² all older individuals, the average number of eosinophils was $0.8 \times 10^9/L$ (range, $0.44 \times 10^9/L$ to $1.72 \times 10^9/L$). Patients 1 and 2, younger infants, showed greater eosinophilia, with absolute eosinophil counts as high as $1.42 \times 10^9/L$ (6 weeks of age) and $1.37 \times 10^9/L$ (12 weeks of age), respectively. Patient 3 had a moderate level of eosinophilia.

Additional findings of HIE include

coarse facial features, usually including a broad nasal bridge, prominent nose, and irregularly proportioned cheeks and jaws as well as changes secondary to *C albicans* infection.^{2,10,11} These manifestations were not present in our patients during their first months of life and usually developed later in the course of the disease. On the other hand, nonspecific findings, including anemia and hepatosplenomegaly, probably reflecting a chronic inflammatory state, were part of their initial presentation of symptoms.

The IgE level as well as specific antistaphylococcal IgE antibodies are two characteristic features of HIE^{3,10} and have not been extensively studied in young infants with the syndrome. In most normal infants, umbilical cord blood IgE levels are undetectable ($<1.0 \mu g/L$). After birth, serum IgE levels rise, along with other immunoglobulins, with maximal values appearing between the ages of 10 and 15 years.¹⁹ The IgE level was elevated in our four patients during their first year of life. Patients 1 and 2 had their first measurement done at 6 to 7 weeks of age (163 and 101 $\mu g/L$, respectively); for patients 3 and 4, it was performed at 8 and 12 months of age, respectively, and was 720 and 3000 $\mu g/L$. In the literature there is also a report of a girl, born to a mother with HIE, who had an elevated umbilical cord blood IgE level of 173 $\mu g/L$; she developed the disease during childhood.²⁰ Although diagnostic criteria in the past have used an IgE level at least 10 times greater than normal ($>5000 \mu g/L$),² a child younger than 1 year of age is unlikely to produce such high levels of this immunoglobulin. This is a finding that is also confirmed in infants from atopic families who further develop allergic diseases: 50% of infants have maintained serum IgE levels below 25 $\mu g/L$ until 1 year of age.²¹ In infants with HIE, IgE levels, although usually 10 times greater than normal for age, are still significantly low both in absolute numbers and relative to values in later childhood; serum IgE level above 5000 $\mu g/L$ should not be a requisite in the newborn period.

Elevated levels of circulating anti-*S aureus* IgE antibodies have been well documented in most patients with HIE. In the original report,³ anti-*S aureus*

IgE antibodies were demonstrated in the sera of patients with HIE but were not detected in patients with atopic skin disease, parasitic infections, and chronic or acute staphylococcal infections and in normal individuals. This was confirmed by Berger et al,⁴ who also demonstrated there were specific anti-*C albicans* IgE antibodies, as did two other groups.^{5,8} They all demonstrated the specificity of anti-*S aureus* IgE antibodies for HIE when compared with other conditions associated with increased serum IgE levels with or without recurrent *S aureus* infections. A recent report of 69 patients with atopic dermatitis showed that most patients did not have detectable levels of IgE antibody to *S aureus*.²² However, Abramson et al²³ and Walsh et al²⁴ reported increased anti-*S aureus* IgE antibodies in patients with atopic skin disease but not to the extent of the in-

crease in patients with HIE. In patients 1 and 2, antistaphylococcal IgE antibodies were detected in the sera in the first 6 months of life and were found only at around 12 months of age for patients 3 and 4. This represents an earlier detection of the anti-*S aureus* IgE antibody than reported by Dreskin and Gallin²⁰ in a young girl, where anti-*S aureus* IgE was first found at 2 years of age. The development of anti-*S aureus* IgE antibodies in infants is variable and seems related to the progression of the disease and the occurrence of severe staphylococcal infections, as it was demonstrated in a group of patients with atopic dermatitis in whom there was a direct correlation between anti-*S aureus* IgE levels and *S aureus* counts in the anterior nares.²⁵ The presence of anti-*S aureus* IgE antibodies may serve as a confirmatory test in infancy when the clinical picture of the syndrome as well

as extremely high IgE levels are not yet fully expressed.

In summary, HIE is a complex disorder that has distinctive features in infancy: a recurrent papulovesicular rash and conspicuous eosinophilia before evidence of overwhelming infection. The presence of both elevated serum IgE levels and anti-*S aureus* IgE antibodies is important in confirming the clinical diagnosis in infants. Early recognition of HIE is of therapeutic relevance since use of prophylactic antibiotics is often clinically helpful.

This work was supported in part by grant HL-27068 from the National Institutes of Health, Bethesda, Md, and by the R. Samuel McLaughlin Foundation, Canada (Dr Lavoie).

We thank Donald E. Campbell, PhD, and the Clinical Immunology Laboratory staff at the Children's Hospital of Philadelphia (Pa), for the assays that they performed; Mary Ellen Conley, MD, for her role in the management of these patients and critical advice; and Sarah Jackson and Shree Lighty for outstanding secretarial support.

is**

FAMILY VIOLENCE

**Learn about the sources,
symptoms and treatment of
this American epidemic.**

From drug use to sexual abuse, all the facts about family violence—and what you as a physician, mental health professional or administrator need to know—will be addressed at the AMA's comprehensive Conference on the Prevention of Family Violence and Victimization. This multi-disciplinary conference, emphasizing current research, policies and practices

involved in the diagnosis and treatment of family violence, includes workshop topics on: The cycle of abuse; spouse, elder and child abuse; the relationship of drugs and alcohol to family violence; and legal and policy issues.

EDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus* var. *capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus* var. *capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combining of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: Teratogenic Effects: Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp (especially behind the ears and on nape of the neck). Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combining of nits is not required for therapeutic efficacy, but may be done for cosmetic reasons or to meet school "no nit" policies. A nit comb is provided.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz., weighing 56 g. (NDC-0081-0780-81)
Store at 15°-25°C (59°-77°F).

STYLE!

AMA MANUAL OF STYLE

The one to consult

Whether it's a multi-volume work or a short article, you'll find the write stuff in the **AMA Manual of Style**.

This 8th Edition, a major revision, is the *standard* among medical publishers. All major aspects of manuscript preparation are covered in five sections which outline: • Preparing an article for publication • Style • Terminology • Measurement and Quantitation • Technical Information and Bibliography.

You'll find everything you need to make your article a success including: • Legal and Ethical Matters • Grammar • Punctuation • Word Use • Foreign Words and Phrases • Diacritics • Abbreviations • Units of Measure • Numbers and Percentages • Mathematics • Statistics • Production and Printing Terms • Editing and Proofreading Marks • Eponyms • Nomenclature • Greek Alphabet • Virus Names • SI Units and Conversion Tables • Expanded Collection of Graphs and Charts • Bibliography • Resources for On-Line Databases.

Next time you have a question about making your medical writing more clear, concise and accurate, be ready with one simple answer — the **AMA Manual of Style**. Order your copy today!

1988/377 pp/4351-X/\$24.95

Treatment of Croup

A Critical Review

Neil S. Skolnik, MD

• Although viral croup is the most common form of airway obstruction in children 6 months to 6 years of age, there is debate regarding medical care for the hospitalized patient. A complete review of the English-language literature from 1960 to 1988 was performed, using both manual and Medline searches. Critical review shows that laryngotracheitis and spasmodic croup, previously emphasized in the literature as having distinct etiologies, most likely are two ends of a broad spectrum in the clinical presentation of a single disease. Critical assessment of all prospective randomized double-blind placebo-controlled trials reported during the study period shows that there is little information on the use of humidified air or supplemental oxygen, that racemic epinephrine hydrochloride is of well-demonstrated efficacy, and that dexamethasone phosphate at a dose greater than 0.3 mg/kg is effective in decreasing the length and severity of respiratory symptoms associated with viral croup.

(AJDC. 1989;143:1045-1049)

Viral croup is the most common form of airway obstruction in children 6 months to 6 years of age. From 1.5% to 15% of children with croup who are seen in an outpatient setting require admission to the hospital, accounting for approximately 20 000 hospital admissions per year in the United States.¹⁻³ During hospitalization, 1% to 5% of children with viral croup require intubation.^{1,3,5}

Although croup is a common illness, there is no consensus about optimal medical management. Mist tents, oxygen, adrenal corticosteroids, and racemic epinephrine hydrochloride are all commonly used treatments. The place and efficacy of these different modal-

ities in the management of croup have been the subject of debate since the early 1960s.^{1,3,6-14} A review of the literature for the last 25 years reveals no single article that critically assesses the efficacy of the various medical treatments of croup. The purpose of this article is to critically review and synthesize the complete body of English-language literature on the medical treatment of croup and formulate a set of recommendations to guide physicians in making treatment decisions for children with croup who require hospitalization. In addition, this article will briefly review the pathophysiological and clinical presentations and differential diagnosis of croup as it relates to treatment decisions; more complete reviews of these areas are available elsewhere.^{1,3,7,9,11}

DATA IDENTIFICATION

A complete review of the English-language literature on the treatment of croup was performed, first by a manual search covering 10 years (1978 to 1988) of the *Index Medicus*, then by reviewing all pertinent references from these articles for the years 1960 to 1988. To ensure completeness of the literature review, this was then checked against a Medline search.

PATHOPHYSIOLOGIC FEATURES

Croup, a syndrome of laryngeal obstruction, is most commonly caused by a viral infection in the subglottic region of the larynx.^{1,3,7,9} The most common virus-causing croup is parainfluenza virus type I. Other less common viral origins include parainfluenza virus types II and III, influenza virus type A, respiratory syncytial virus, and the rhinoviruses.^{1,2,7,9} When the subglottic region of the larynx, held rigidly within the ring of the cricoid cartilage, becomes infected, there is edema of the subglottic region, which leads to narrowing of the

airway. Since the infant's larynx is normally very narrow, a small decrease in the radius of the airway due to edema leads to a large decrease in the area available for air flow. This causes obstruction of air flow, stridor, and shortness of breath.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The mean age of children presenting with viral croup is approximately 18 months, with a range from 3 months to 5 years.⁷ Boys are affected more often than girls. There is seasonal occurrence, with a dramatic increase in cases beginning in early autumn and continuing into the winter months.^{2,15} Croup is usually preceded by an upper respiratory tract infection, and as the subglottic region becomes involved, a characteristic "croupy" or barking cough develops. As obstruction progresses, inspiratory stridor develops and becomes associated with flaring of the ala nasi, suprasternal retractions, and intercostal retractions.

Physical examination usually shows a child in minimal to severe respiratory distress, with varying amounts of fever, dyspnea, inspiratory stridor, flaring of the ala nasi, intercostal and suprasternal retractions, and a barking "seal-like" cough. Lungs are usually clear to auscultation, with transmitted upper airway sounds, though there may occasionally be mild wheezing. Laboratory examination reveals a normal or mildly elevated white blood cell count, with white blood cell counts in excess of $15 \times 10^9/L$ occurring in about 20% of patients with croup.¹⁵ Posteroanterior roentgenograms of the neck classically show a narrowed subglottic region with a "steep" sign indicative of subglottic narrowing. On lateral neck roentgenograms there may be a widening of the hypopharynx. Classic signs of croup ap-

pear on the roentgenogram in only 40% to 50% of cases.^{8,15,16}

The differential diagnosis of croup includes a number of life-threatening illnesses, including epiglottitis, aspiration of a foreign body, and retropharyngeal abscesses. Other diseases to be considered in the differential diagnosis are peritonsillar abscesses, bacterial tracheitis, acquired or congenital subglottic stenosis, infectious mononucleosis, paraquat poisoning, and laryngeal lymphoma. Excellent reviews have been written on the differentiation of croup from epiglottitis.^{1,3,7,9,16}

SPASMODIC CROUP VS LARYNGOTRACHEITIS

The diagnosis of croup has traditionally included the distinction between spasmodic, or recurrent, croup (SC) and laryngotracheitis (LT). Some researchers have felt that this distinction is important because SC may improve rapidly with or without treatment.^{6,8} Though the terms have existed for a long time, there is a paucity of literature to support this distinction. The clinical distinction between SC and LT in the literature is not clear. Spasmodic croup is described as occurring with or without a preceding upper respiratory tract infection, occurring at night, being abrupt in onset, and being generally mild in its course. Laryngotracheitis is described as occurring after a preceding upper respiratory tract infection, occurring at night, having severity that worsens quite rapidly or over a period of hours, and being mild or severe. Both forms of croup occur in children of the same age group and are associated with the same respiratory viruses.^{3,8,17,18}

Some authors have suggested that SC differs from LT in that SC may be an allergic reaction to viral antigens rather than a true infection with the virus as in LT.¹³ Two studies have been used to support this theory, and both have serious flaws. In one, children who had a history of "recurrent croup" had a higher incidence of allergy than children with a history of nonrecurrent croup when studied 9 years after their last admission to the hospital.¹⁹ In the other, children older than 6 years of age, hospitalized with recurrent croup during the previous 12 months, had significantly greater airway hyperreactivity to hista-

mine challenge than a group of healthy controls.²⁰ Both of these studies suggest that children who have an allergic predisposition may have more upper respiratory tract infections or more-severe upper respiratory tract infections, leading to repeated hospitalization, but neither convincingly shows a difference in the cause of SC from that of LT.

Spasmodic croup and LT display a large overlap of symptoms, clinical presentation, and viral origin. The pathophysiology of subglottic edema leading to upper airway obstruction is the same for the two entities.^{8,9} No study has convincingly shown that the underlying causes differ, nor has any study been able to give good, reliable criteria to prospectively separate the two entities.^{13,17-19} Laryngotracheitis and SC most likely are two ends of a broad spectrum in the clinical presentation of a single disease.

TREATMENT

The most important aspects of the treatment of croup are arriving at the correct diagnosis, assessing the severity of the disease, and providing careful observation for deterioration of the hospitalized patient. Once the diagnosis of viral croup has been made, therapeutic options include humidified air, oxygen therapy, racemic epinephrine, and corticosteroids. All of the published studies on the treatment of croup have examined a cohort of patients needing hospitalization due to severe croup; therefore, the recommendations that follow apply only to patients hospitalized with croup, and one must be cautious in generalizing this information to the ambulatory setting.

Humidified Air and Oxygen

Humidified air, with and without supplemental oxygen, is often provided by a mist tent as a routine part of treatment for any child hospitalized with croup. Inhalation of moist air in the treatment of croup has its roots in the late 19th century, when parents found that steam from tea kettles or hot tubs helped break the spasms of croup. This empiric observation led to the use of "croup kettles" in hospitals.³

Humidified air presumably works through two mechanisms. It moistens secretions, making it easier for the child

to bring them up, and it soothes inflamed laryngeal mucosa, making the child feel more comfortable. This may diminish submucosal irritation by helping to decrease the amount of coughing. There are no data showing any effect of humid air on subglottic edema, the main pathophysiologic defect in croup.

Two studies have looked at the effectiveness of moist air in the treatment of croup. One showed no improvement in total respiratory resistance when measured before and after the administration of 2 mL of nebulized sterile water in 5 children.²¹ The other assessed 16 consecutive patients randomly assigned to receive no treatment other than observation in a normal hospital environment (relative humidity, 48% to 52%) or treatment with a mist tent (relative humidity, 87% to 95%). Results showed no benefit of treatment in a mist tent over control when patients were assessed for 12 hours.²²

Henry,²³ in an elegant commentary on the use of humidified air for croup, contends that the improvement seen when a child is held in its mother's arms near a steamy shower may be due as much to the "comfort and reassurance" that the child has in that environment as to the steam. He feels that without evidence to the contrary, separating a child from its parents to put it in a mist tent is more distressing to the child than it is helpful.

The use of oxygen in croup is controversial. In one study that measured arterial blood gas values in children admitted to the hospital with the diagnosis of croup, 29 of 35 children were found to be hypoxemic.²⁴ In these individuals, hypoxemia more closely correlated with respiratory rate, and the degree of observed stridor was an unreliable indicator of hypoxemia. There are a number of possible causes for this observed hypoxemia: (1) direct infection of lung parenchyma with parainfluenza virus, leading to impaired diffusion capacity in the lung; (2) ventilation/perfusion mismatch, secondary to direct infection of lung parenchyma; and (3) pulmonary edema, secondary to the negative intrathoracic pressure occurring during inspiratory airway obstruction.²⁵ There has been no controlled trial of the use of supplemental oxygen in croup, so there are no data on which to make a decision for or against the use of oxygen in a

*NS indicates normal saline solution; IPPB, intermittent positive pressure breathing.

†The effect of epinephrine in the treatment of viral croup had a positive (plus sign) or negative (minus sign) outcome.

clinical setting. Since it is difficult to achieve oxygen concentrations above 40% in a mist tent, oxygen is unlikely to be of any detriment and may be of some theoretical advantage.

In summary, there is no evidence that humidified air or supplemental oxygen is of benefit to children hospitalized with croup. Based on anecdotal evidence, it is prudent to maintain reasonable humidity in the hospital room. This is easily and comfortably provided for by a portable humidifier. Given the large amount of anecdotal evidence, it is not unreasonable to use a mist tent, with or without supplemental oxygen, as long as it is well tolerated by the child.

Racemic Epinephrine

Racemic epinephrine administered by a nebulizer, either with or without intermittent positive pressure breathing, has frequently been used since its introduction by Adair³ in 1971. Racemic epinephrine is believed to work via its α -adrenergic effects. α -Adrenergic stimulation causes mucosal vasoconstriction, leading to decreased edema in the inflamed subglottic region.³

Five prospective studies have evaluated the efficacy of racemic epinephrine in the treatment of croup (Table 1). All five were double-blind placebo-controlled trials that assessed drug effect through scoring systems of clinical variables that reflect airway obstruction. The scoring systems assess level of consciousness, stridor, color, retractions, cyanosis, croupy cough, and dyspnea. Four of the five studies concluded that racemic epinephrine decreases airway

obstruction.^{17,26-28} The only study showing no effect of racemic epinephrine on airway obstruction failed to specify how long after administration of the medication assessment of the patient was carried out.²⁹ As discussed below, it is possible that a transient effect of racemic epinephrine could have been missed if patient assessment was carried out more than 1 to 2 hours after administration of the medication.

Three studies assessed the duration of effect of racemic epinephrine. These studies showed a significant decrease in airway obstruction when measured within 30 minutes of treatment. The degree of obstruction returned to baseline level or above by 2 hours after administration of the medication.²⁶⁻²⁸ Treatment with racemic epinephrine appears to cause a rebound effect in some patients, with the degree of obstruction becoming greater 2 hours after treatment than it was before administration of the drug.

In summary, the evidence from four of five clinical trials supports a strong effect of racemic epinephrine in decreasing airway obstruction from 10 to 30 minutes after administration. This effect wanes over time and disappears by 2 hours after administration, with rebound effects in some cases. Nebulizer rather than intermittent positive pressure breathing is recommended for administration of racemic epinephrine since there is no evidence showing intermittent positive pressure breathing to be superior to nebulization. In addition, nebulization is tolerated better and has less risk than intermittent positive pressure breathing.²⁶

Adrenal Corticosteroids

The efficacy of adrenal corticosteroids in the treatment of croup has been debated since first introduced for croup in the early 1960s. Theoretically, corticosteroids may decrease subglottic edema by suppressing the local inflammatory reaction, by shrinking lymphoid swelling, and by decreasing capillary permeability.^{3,30,31} Twelve studies, from 1960 to 1988, have assessed the efficacy of adrenal corticosteroid use in viral croup. These studies have yielded conflicting results (Table 2).

Tunnessen and Feinstein,⁶ in an analytical review of corticosteroid treatment of viral croup, have pointed out major methodologic problems in studies reported through 1978. They concluded that controversy over the efficacy of corticosteroids in the treatment of croup arises from inadequacies in the performance of three methodologic strategies: (1) establishment of diagnostic criteria for croup, the main problem being the lack of separation of SC from LT; (2) adequacy of corticosteroid dosage; and (3) choice of the outcome event. Tunnessen and Feinstein defined an adequate choice of outcome event to be "Relief in the severity of the obstructive symptoms . . . represented by a reduction in the summation score for severity of signs and symptoms of croup, such as stridor, retractions, cyanosis, and pulse and respiratory rates, rather than changes in individual signs and symptoms."⁶

An inadequate choice of outcome events seems to have been a serious problem in the studies performed be-

†The effect of corticosteroids in the treatment of viral croup had a positive (plus sign) or negative (minus sign) outcome or both (plus/minus sign).

fore 1969. These same studies all also used inadequate doses of corticosteroids.³²⁻³⁶ The distinction of SC from LT has been discussed extensively in the section above and, as outlined, is unlikely to have contributed to the conflicting results in different studies. The major methodologic strategy that has led to conflicting results among reported clinical trials is the use of differing doses of corticosteroids.

Six studies have used a dose of corticosteroids less than 0.2 mg/kg of dexamethasone phosphate or its equivalent.³²⁻³⁷ While these studies do have methodologic flaws,⁶ five of them showed that corticosteroids have no effect on outcome (Table 2).

Six studies have used a dose of corticosteroids greater than 0.3 mg/kg of dexamethasone phosphate or its equivalent.^{15,17,18,38-40} To assess the efficacy of corticosteroid treatment, it is this group of studies that is best examined. Each of these six studies was a prospective randomized double-blind trial and, with one exception,¹⁸ used well-defined clinical scoring systems, rating levels of stridor, retractions, tachycardia, dyspnea, cyanosis, and respiratory rate to

define outcome. Four of these six studies showed a significant beneficial effect of corticosteroids when compared with placebo.^{15,17,38,40} The two studies that did not report a significant beneficial effect of an adequate dose of corticosteroids deserve further comment.

The study by Skowron et al,³⁹ which concluded that corticosteroids provide no significant benefit in the treatment of croup, showed a strong trend in favor of a beneficial effect. Corticosteroids were shown to be significantly more effective than placebo in four of seven clinical parameters measured. In the other three parameters measured there was a strong trend, not reaching significance, in favor of corticosteroid use.

The only study that has used a dose of dexamethasone phosphate greater than 0.3 mg/kg that does not support the effectiveness of corticosteroids has two major methodologic deficiencies.¹⁸ First, all patients enrolled in this trial were given chloral hydrate at a dose of 75 mg/kg. The use of sedative medication is not a usual or accepted mode of treatment for patients in respiratory distress, and it is not known how sedatives affect outcome and evaluation of

patients with croup. Second, respiratory rate, measured for 6 hours, was the only parameter monitored to assess patient response. Respiratory rate is not as sensitive an indicator of upper airway obstruction as are the summation scores of respiratory distress that were used in the other six studies that used an adequate dose of corticosteroids. In addition, a dose of corticosteroids administered on admission does not reach maximum effect until 6 hours later.⁸¹ Most studies that have documented a response to corticosteroid administration have shown that clinical status improves over a 12- to 24-hour period,^{15,38} though the study by Kuusela and Vesidari¹⁷ showed a significant difference at 6 hours after administration.

In summary, four of six prospective randomized trials using an adequate dose of adrenal corticosteroids showed a statistically significant benefit of corticosteroids in decreasing the length and severity of respiratory symptoms when compared with placebo in the treatment of viral croup. One of the two trials that did not show a significant difference between corticosteroids and placebo showed a strong trend in favor of a bene-

ficial effect of corticosteroids. The only study that did not show corticosteroids to be effective in croup had serious methodologic flaws.

Four prospective trials using an adequate dose of corticosteroids have assessed length of hospital stay. Three of these studies showed a decrease in length of stay for children treated with corticosteroids.^{15,17,38,39} The efficacy of repeated doses of corticosteroids has not been examined in any study. Since the adverse effect of a short course of corticosteroids is very small^{20,41} and no study of corticosteroid use in croup has reported any adverse effects related to corticosteroid use, it seems that the evidence is overwhelmingly in favor of recommending intramuscular administration of dexamethasone phosphate in a dose of 0.6 mg/kg to be given on admission to any child admitted to the hospital with a diagnosis of viral croup. This is consistent with a recent meta-analysis of randomized trials assessing the use of corticosteroids in viral croup.⁴²

Antibiotics

Viruses are the causative agent in most cases of infectious croup.^{1,3,7,9} Once a careful diagnostic workup is completed and causes other than viral croup, including epiglottitis, bacterial tracheitis, and retropharyngeal abscess, are ruled out, there is no evidence that antibiotics are of any benefit in the treatment of viral croup; nonetheless, antibiotics continue to be used. In a retrospective chart review preformed in North Carolina from 1977 to 1981, 58% of patients admitted with a diagnosis of croup received antibiotics, usually ampicillin sodium.¹⁶

In the absence of other aspects of the clinical picture that suggest a bacterial process, there is no reason to use antibiotics in the treatment of hospitalized patients with infectious croup.

CONCLUSION

A rational approach to the treatment of the child with severe croup requiring hospitalization is to use a combination of humidified air, racemic epinephrine, and adrenal corticosteroids, all given under careful observation. Humidified air, though not of proved benefit, may be provided by a mist tent, with or without oxygen, or by a humidifier placed in the child's room. Racemic epinephrine,

administered by nebulizer in a dose of 0.25 mL of 2.25% racemic epinephrine hydrochloride in 2 to 3 mL of normal saline solution, given on admission and then every 2 hours as needed, has well-established efficacy and can help to decrease the degree of laryngeal obstruction during the early hours of admission, before the corticosteroids have begun to take effect. Dexamethasone phosphate, 0.6 mg/kg given intramuscularly on admission, is well supported in the literature to be effective in the treatment of obstructive airway symptoms due to croup, and there is some suggestion that it may decrease length of hospital stay.

The author gives special thanks to Howard Rabinowitz, MD, and Richard Brown, MD, for their encouragement and critical thoughts at varying stages during the preparation of the manuscript.

Available to more patients
ever before

AeroChamber® with MASK (aerosol holding chamber)

Easier metered-dose inhaler (MDI) therapy in children and the elderly (see boxed statement below). The device consists of an aerosol holding chamber with a soft, flexible mask that fits over the patient's nose and mouth. A one-way valve holds the medication in the chamber for the patient to inhale. Expired air is vented through the exhalation port. AeroChamber with Mask is economical and fits virtually any inhaler.

IMPORTANT INFORMATION

Always insert dosing instructions should be consulted for all metered-dose inhalers (MDIs) when used with AeroChamber with Mask.

Usage and administration recommendations vary for different MDIs, and the limitations and conditions of use for this product should be considered before utilizing this device, especially for younger and older patients.

If you are interested in the AeroChamber® with Mask. Please send more information.

RE-INTRODUCE THE OLDEST ADVANCE IN MEDICINES.

It's called talking. If your older patients don't ask you about the prescriptions they've been given, make it a point to tell them what they need to know. Make sure they know the medicine's name, how and when to take it, precautions, and possible side effects. Encourage them to write down the information and ask you questions about things they don't understand.

You'll also want to take a complete medications history including both prescription and non-prescription medicines. The history can alert you to the potential for drug interactions and help you simplify their regimen.

Re-introduce the oldest advance in medicines. Make talking a crucial part of your practice. Because good, clear communication about medicines isn't a thing of the past. It's the way to a healthier future.

*Before they take it,
talk about it.*

Corticosteroids as Adjunctive Therapy in Bacterial Meningitis

A Meta-analysis of Clinical Trials

Peter L. Havens, MD, MS; Karen J. Wendelberger, MD; George M. Hoffman, MD; Martha B. Lee, PhD; Michael J. Chusid, MD

• A meta-analysis of all nine available controlled trials of corticosteroids for adjunctive therapy for bacterial meningitis was performed. Risks of various outcomes were assessed for control and treatment groups from each study, and risk differences were determined. For each outcome a weighted average of the individual risk differences was calculated. The results show that corticosteroid administration did not reduce the risk of death or neurologic abnormality at hospital discharge or follow-up examination. Based on statistically combined results of the three most recent trials, there is evidence that dexamethasone reduces the risk of bilateral moderate or more severe hearing loss (risk difference, -9%; 95% confidence limits, -15% and -3%). However, this may be true only for children with meningitis caused by *Haemophilus influenzae* type b. There are inadequate data in adults or in children with meningitis due to other organisms to demonstrate the benefit of dexamethasone administration. Further study is necessary to fully assess the benefits and risks of corticosteroids for adjunctive therapy for bacterial meningitis.

(AJDC. 1989;143:1051-1055)

Acute bacterial meningitis remains a potentially devastating illness. Despite improvements in antimicrobial chemotherapy and supportive patient care, the case fatality rate remains 1% to 8%.¹⁻⁵ The rate of serious neurologic sequelae is 10% to 30%,⁶⁻¹² and the rate of hearing loss is 5% to 31%.^{10,11,13-16}

Corticosteroids have been employed as adjunctive treatment of bacterial

meningitis in the hope of reducing the rates of hearing loss and other neurologic sequelae.¹⁷⁻³⁰ While results of one recently published study suggest that corticosteroid therapy may reduce hearing loss following acute bacterial meningitis,²⁹ other studies have demonstrated no benefit^{25,26,28,30} or have suggested that in patients treated with corticosteroids, the outcome is worse than in control patients.^{18,24}

When there are multiple studies with conflicting results, therapeutic decisions can be difficult to make. Meta-analysis, "the statistical analysis of a collection of analytic results for the purpose of integrating the findings,"³¹ offers useful techniques to approach this problem.^{32,33} We have used meta-analysis to evaluate the efficacy of corticosteroids in acute bacterial meningitis by pooling the results of the available controlled clinical trials.

MATERIALS AND METHODS

To obtain reports of the use of corticosteroids in treatment of acute bacterial meningitis, we performed a computer search of the English-language literature from 1966 through 1988 using Medline. We also reviewed the bibliographies of the articles obtained by the computer search as well as the bibliographies of reviews of the therapy for bacterial meningitis.³⁴⁻³⁸

All studies were reviewed by all of us. Only randomized, concurrently controlled trials were included in the meta-analysis. Data were abstracted in a blind fashion by three of us (K.J.W., G.M.H., and M.J.C.), and discrepancies in evaluation were resolved by group consensus. Data regarding the following end points were sought from each study: death, definite neurologic abnormality at discharge and at follow-up examination, and hearing loss at follow-up examination.

For each trial the risk of each specific outcome was calculated as the proportion of af-

fected individuals in treatment or control groups. The risk difference (RD, risk in the treatment group minus risk in the control group) was calculated for each outcome in each study.³⁹ When RD is calculated in this fashion, a negative value suggests treatment benefit. Ninety-five percent confidence limits (CLs) were calculated for all proportions.³⁹ When the 95% CLs of the RD include 0, no statistically significant difference exists.

The results of all the trials were combined by two different methods. First, for each outcome the number affected and group totals were summed, and the RD was calculated from that simple sum. In addition, the RDs were combined using the method of DerSimonian and Laird⁴¹ to give a "weighted average" RD and variance. This method gives less weight to studies with larger variances and to studies with RDs further from the mean of the others. Since only studies with similar methods were combined, a test for homogeneity of the RDs was not performed.³²

We combined all reports with data available on each outcome. We also analyzed the subgroup of five studies that were performed primarily in children.^{24,25,29,30} This separates the "pediatric studies" from three studies carried out primarily in adults^{18,21,28} and one study restricted to adults and children with meningitis caused by *Streptococcus pneumoniae*.²⁶

RESULTS

Fourteen reports of corticosteroid use in acute bacterial meningitis in human subjects were found. Uncontrolled^{17,19,22,27} or retrospective²³ series were excluded. One series²⁰ was excluded because it duplicated a previous report.¹⁸ One report²⁸ included results of two different trials, each of which is considered separately. Not all reports contained data regarding all of the end points of interest; these deficiencies are reflected in the tables and figures.

Total	(379)	(257)	(117)	...

*The sum (753 patients) is lower than the total number of patients in the studies because some patients had other organisms cultured or had sterile spinal fluid.

Table 1 shows the specifics of the nine clinical trials that were included in the meta-analysis.^{18,21,24-26,28-30} Assignment to treatment or control group was random in seven, by date of birth in one, and by alternate patient in one. Six of the studies were blind and placebo-controlled. The corticosteroid dosage used was variable, as shown in Table 1. The lowest dosage given was equivalent to 2.5 mg of hydrocortisone per kilogram daily¹⁸; the highest dosage was equivalent to 15 mg of hydrocortisone per kilogram daily.^{29,30} The studies included a total of 846 patients with meningitis: 379 (45%) with *Haemophilus influenzae* type b, 257 (30%) with *S pneumoniae*, 17 (14%) with *Neisseria meningitidis*, and 93 (11%) with other, undetermined, or unstated causal agents. For the 470 patients in the studies performed pri-

marily in children,^{24,25,29,30} the causative organisms were as follows: 322 (69%) with *H influenzae* type b, 45 (10%) with *S pneumoniae*, 59 (13%) with *N meningitidis*, and 44 (9%) with other, undetermined, or unstated organisms.

The mortality rate was not changed by corticosteroid use. One study excluded patients who died.³⁶ In the eight remaining studies, the median case fatality rate was 4.5% in the corticosteroid-treated group and 2% in the control group. The RD for death varied from -16% to 18%. When the risk differences from these eight studies were combined,³¹ the weighted average RD was 0.9% (95% CLs, -2% and 4%). For the pediatric studies, the weighted average RD was 0.1% (95% CLs, -3% and 3%).

The percentage of individuals with a

definite neurologic abnormality evident at the time of hospital discharge was significantly decreased in corticosteroid-treated patients in one study (RD = -17%; 95% CLs, -32% and -2%).²⁹ Conversely, another study¹⁸ demonstrated a statistically significant increase in patients with a definite neurologic abnormality in the corticosteroid treatment group (RD = 10%; 95% CLs, 2% and 19%). Five studies^{24-26,29,30} showed no statistically significant difference in neurologic status at hospital discharge between treatment and control groups (range of RDs, -15% to 5%). For the seven studies with information available on neurologic outcome at hospital discharge, the combined RD was 0.2% (95% CLs, -11% and 12%, Fig 1). For the five pediatric studies, the combined RD was -9% (95% CLs,

Fig 1.—Risk of neurologic abnormality at hospital discharge. Asterisk indicates weighted combination of the risk differences for all the studies³¹; dagger, weighted combination of the risk differences for data from the pediatric studies.^{24,25,29,30}

Fig 2.—Risk of neurologic abnormality at follow-up examination. Asterisk indicates weighted combination of the risk differences.³¹ The only studies reporting on neurologic status at follow-up examination were done with pediatric patients.

—20% and 1%.

Information concerning definite neurologic abnormalities at a follow-up examination at least 6 weeks after hospital discharge was available from five studies, all of which were carried out in pediatric patients (Fig 2). One study²⁴ showed a statistically significant detrimental effect of corticosteroid treatment (RD=13%; 95% CLs 1%, and 26%). Four trials^{25,29,30} showed no statistically significant difference between the treatment and control groups. When all studies were combined, the

overall RD was -3% (95% CLs, -11% and 5%).

Auditory function was assessed in only three trials (Table 2).^{29,30} Hearing tests were generally done within 6 weeks of hospital discharge, although the exact timing of the follow-up examinations cannot be determined from the published reports of two of the studies.²⁹ One trial showed a significant decrease in bilateral moderate or more severe hearing loss in the dexamethasone-treated group (RD = -16%; 95% CLs, -30% and -2%). The other two trials

showed an effect in the same direction that did not reach statistical significance.^{29,30} When these three trials are combined, the result favors steroid use, as the RD is -9% and the 95% CLs do not include 0 (-15% and -3%).

Complications of corticosteroid administration were not reported in most of the studies. There were three superinfections in the steroid group in one study.¹⁸ Gastrointestinal tract bleeding of sufficient severity to require blood transfusion developed in two patients who received corticosteroids.²⁹ One dexamethasone-treated patient had positive cerebrospinal fluid cultures after 10 days of antibiotic therapy.²⁹

COMMENT

Based on our analysis, there are insufficient data to support the routine use of corticosteroids as adjunctive therapy for patients with bacterial meningitis. The risk of moderate or more severe bilateral hearing loss is lower in patients treated with dexamethasone, based on pooled results from the three studies that assessed auditory acuity. However, combined results from nine available trials show no benefit of corticosteroid administration on risk of mortality, neurologic abnormality at hospital discharge, or neurologic abnormality at follow-up examination. These results do not change when separate analyses are done with data from studies performed only in children.

Meta-analysis can be a useful technique for combining results from multiple small studies with conflicting results.^{32,33} Optimally, studies included should be randomized, placebo-controlled, and double-blind. They should evaluate the same therapy in populations that are similar in age, disease, and disease severity. The same outcomes should be measured in similar fashion at similar follow-up times and should be reliably recorded.³³ The studies included in our meta-analysis do not meet all these criteria. The trials were carried out over 31 years, from 1958 through 1988. While they all employed concurrently treated control patients (by design), only six were placebo-controlled or double-blind. The corticosteroid type and dosage were different in all but three of the studies. The antibiotic type and dosage were different in all

Table 2.—Risk of Moderate or More Severe Bilateral Hearing Loss

Source, y	Risk, No. Affected/ Total in Group (%)		Risk Difference, % (95% Confidence Limits)*
	Treatment Group	Control Group	
Lebel et al (group 1), ²⁹ 1984-1985†	2/43 (5)	8/38 (21)	-16 (-31, -2)
Lebel et al (group 2), ²⁹ 1986-1987‡	1/49 (2)	5/46 (11)	-9 (-19, 1)
Lebel et al (group 3), ³⁰ 1987-1988§	1/30 (3)	2/29 (7)	-4 (-15, 8)
Total	4/122 (3)	15/113 (13)	-10 (-17, -3)
Combined risk difference¶	-9 (-15, -3)

*The risk in the treatment group minus the risk in the control group equals the risk difference. When the 95% confidence limits of the risk difference include 0, no statistically significant difference exists.

†Cefuroxime sodium, 240 mg/kg per day, was used for antibiotic therapy.

‡Ceftriaxone sodium was used for antibiotic therapy.

§Cefuroxime sodium, 300 mg/kg per day, was used for antibiotic therapy.

||The risk difference was calculated for each study separately using the method of Fleiss.³⁹

¶The risk difference was calculated for all the studies combined using the method of DerSimonian and Laird.³¹

of the studies. The populations studied differed in distribution of patient ages and causal agents. Outcome definitions were often not clearly stated, making it impossible to evaluate all the outcome variables of interest in many of the studies. The time to follow-up evaluation was extremely variable. Since neurologic abnormalities may resolve with time,⁴⁰ this could have a significant impact on the results of the trials we pooled.

To avoid some of the problems of combining data from studies carried out in different populations, we did separate analyses on data from five studies done primarily in children.^{24,25,29,30} *Haemophilus influenzae* type b was the cause of meningitis in 68% of cases in this group compared with 45% of cases overall and 15% of cases in the remaining four studies.^{18,21,26,28} There was no significant difference in the results when this subset was analyzed separately from all the other studies.

The results of this overview suggest that corticosteroid administration decreases the risk of hearing loss following bacterial meningitis. Three trials from a single institution assessed auditory acuity.^{26,30} All three employed dexamethasone as the therapeutic corticosteroid. One trial, using the antibiotic cefuroxime sodium at a dosage of 240 mg/kg per day for treatment of meningitis, showed

a significant reduction in hearing loss in the dexamethasone-treated group.²⁹ Another trial, using a higher dosage of cefuroxime sodium (300 mg/kg per day), showed no significant benefit from using corticosteroids.³⁰ The third study, using ceftriaxone sodium, also did not show a statistically significant benefit from dexamethasone.³⁰ The major difference in these studies is the incidence of moderate or more severe bilateral hearing loss in the placebo groups (Table 2), which varied from 21% in the lower-dosage cefuroxime trial²⁹ to 7% in the higher-dosage cefuroxime trial.³⁰ While the difference in these rates is not statistically significant ($\chi^2=2.6$, $P=.11$), a rate of moderate or more severe bilateral hearing loss of 21% is higher than the 6% to 15% incidence found in most recent studies of hearing loss following acute bacterial meningitis.^{13-15,41,42} This suggests that antibiotic choice and dosage may be important factors in the development of hearing impairment following bacterial meningitis.⁴³

Delayed sterilization of the cerebrospinal fluid may be a complication of corticosteroid use. In the one trial by Lebel and colleagues²⁹ that showed significant benefit from dexamethasone administration, cefuroxime was the antibiotic used to treat all patients. While cefuroxime penetrates well into

the cerebrospinal fluid when the meninges are inflamed, penetration becomes poorer as inflammation subsides.⁴⁴ Treatment with dexamethasone, which reduces meningeal inflammation, may result in decreased antimicrobial penetration into the cerebrospinal fluid, with failure to sterilize the cerebrospinal fluid. One patient in this trial²⁹ had a positive cerebrospinal fluid culture after 10 days of cefuroxime plus dexamethasone therapy. This relapse rate is similar to the 0.8% rate reported in a series of 708 patients with *Haemophilus meningitis* who did not receive corticosteroids.⁴⁵ However, persistently positive cerebrospinal fluid cultures have been reported in other patients treated with dexamethasone and penicillin for pneumococcal meningitis.⁴⁶ If corticosteroids improve hearing at the expense of adequate antimicrobial treatment of the underlying disease, the potential benefits do not outweigh the risks.

Other complications of corticosteroid use were poorly reported in most of the studies. Superinfection and gastrointestinal tract bleeding are possible,^{18,29} and it may be that patients treated with corticosteroids should also be treated with antacids, H₂ blockers (cimetidine or ranitidine), or sucralfate to protect against the possibility of serious gastrointestinal tract bleeding.

The findings of this meta-analysis do not support the routine use of corticosteroids in patients with bacterial meningitis. There is preliminary evidence that use of dexamethasone may decrease the incidence of hearing loss, but this is based on combined results of one positive and two negative studies done only in children. Seventy-seven percent of patients in those studies had meningitis caused by *H influenzae* type b. Generalization to meningitis caused by other organisms or to neonates and adults is not justifiable based on available data. If corticosteroids are used as adjunctive therapy to decrease the inflammation associated with bacterial meningitis, antibiotics with adequate cerebrospinal fluid penetration should be used to assure eradication of the infectious agent.

Symmetrical Thalamic Degeneration With Calcifications of Infancy

Francis J. DiMario, Jr, MD, Robert Clancy, MD

• We describe the clinical and radiographic features of three premature infants with symmetric thalamic calcification recognized by computed tomographic scan on days 6, 12, and 49 of life and contrast our findings with those reported in the literature. These lesions follow prepartum or intrapartum hypoxia-ischemia and are clinically distinguished by prominent bulbar dysfunction, featuring weak or absent cry, poor feeding, and facial weakness. Neonatal thalamic calcification in premature infants may serve as a radiological marker of an acute, short-lived hypoxic-ischemic event. The presence of brain-stem dysfunction, particularly of lower cranial nerves in association with thalamic calcifications, constitutes a distinctive clinical-radiological entity and usually portends a poor outcome. The presence of these calcifications implies that injury was sustained to diencephalic and brain-stem structures at least 2 to 4 weeks prior to their appearance on computed tomographic scan.

(AJDC. 1989;143:1056-1960)

There are several patterns of brain injury that may follow hypoxia-ischemia in the human newborn. Different pathophysiologic mechanisms have been proposed to explain the spatial topography of neuropathologic disease and its corresponding clinical correlates.

The rather distinctive clinical and pathological features of hypoxic-ischemic injury maximally involving the diencephalon and brain stem have been infrequently reported.^{1,2} The radiological correlates of this pattern of central nervous

system damage are even less well characterized, and premorbid identification of these calcifications by neuroimaging has been rare.^{4,7,9-11} Neuronal loss and calcification have been identified at autopsy within the thalamus and brain stem in only a few previously reported cases.^{1,8} Similar lesions have been reported only once within the first week of life.⁶ We describe three new cases of this rare but dramatic entity and contrast our patients with those described in the literature. We emphasize the occasional presence of prepartum-onset hypoxia-ischemia, the need for early computed tomographic (CT) imaging, the prominent and persistent clinical signs of bulbar dysfunction, and the uniformly poor neurologic prognosis.

PATIENT REPORTS

PATIENT 1.—A female infant was born via spontaneous vaginal delivery at 35 weeks' gestation after a pregnancy complicated by polyhydramnios. Apgar scores were 8 at 1 minute and 8 at 5 minutes. She required no delivery room resuscitation. The birth weight was 2450 g (45th percentile) and her head circumference was 33 cm (60th percentile). There were no dysmorphic features. From the time of birth she displayed little spontaneous activity and was not visually attentive. Brain-stem abnormalities were prominent. Eye movements were full and intermittent ocular bobbing was noted. She had symmetric but reduced spontaneous facial movements. There was a weak cry, minimal tongue movements with no fasciculations, and absent gag, suck, and swallow. She was mildly hypotonic and maintained a frog-legged posture. Deep tendon reflexes were brisk with several beats of ankle clonus bilaterally. No seizures or involuntary movements were observed. At 6 days of age, an electroencephalogram (EEG) was normal and a CT scan of the head revealed bilateral thalamic calcifications and a small right frontal subdural hematoma (Figure, top). Examination at 8 weeks of age revealed a more vigilant infant with improved spontaneous movement. There was no visual fixation. Extraocular movements were full with a diver-

gent gaze in primary position. The infant continually drooled. Absent gag, suck, and swallow persisted, necessitating nasogastric gavage feedings. She gradually assumed an arched truncal posture with increased extensor tone of all extremities and subsequently developed seizures requiring long-term anticonvulsant therapy. She remains severely impaired neurologically at 30 months of age with spastic quadriplegia, failure to thrive, and marked global delay with motor and mental development below a 3-month level.

PATIENT 2.—A female infant, the 2280-g (60th percentile) product of an uncomplicated 33-week gestation, was born via vaginal delivery in breech presentation. Apgar scores were 2 at 1 minute and 5 at 5 minutes. She was severely depressed at birth, requiring immediate intubation and resuscitation in the delivery room but was extubated within several hours. She required intravenous anticonvulsant therapy with phenobarbital sodium, phenytoin sodium, and paraldehyde for status epilepticus noted at 8 hours of life. Examination revealed a normocephalic (head circumference 31 cm; 50th percentile) nondysmorphic infant who had little spontaneous movement. She was not alert and would not visually fixate. She had a very poor suck, no gag, and was diffusely hypotonic with an absent Moro's reflex. An EEG obtained at 2 days of age was extremely low voltage, evolved into a burst-suppression pattern by 4 days of life, and displayed multifocal spikes and sharp-waves with diffuse slowing by day 12 of life. A head CT scan then suggested brain-stem atrophy and revealed diffuse calcification in the thalami and brain stem (Figure, center). She required nasogastric gavage feedings and ultimately a gastrostomy tube for nutrition. Subsequent ophthalmologic examination at 3 weeks of age revealed optic atrophy bilaterally. At age 6 months, she developed infantile spasms and a hypsarrhythmic EEG. At a 40-month follow-up visit, she had microcephaly, severe spastic quadriplegia, and profound psychomotor retardation.

PATIENT 3.—A female infant was born after 33 weeks' gestation. The pregnancy was complicated by first-trimester maternal treatment of ulcerative colitis with sulfasalazine and the identification by fetal ultrasound examination of a neck mass that suggested

Patient 1 (left) and patient 2 (center). Noncontrast computed tomographic scan of the head, axial view. Note bilateral thalamic calcifications (arrows). Patient 3 (right). Noncontrast computed tomographic scan of the head, axial view. Note bilateral thalamic calcifications (arrowheads) and hypodense parieto-occipital cortices.

the presence of a cystic hygroma. An amniocentesis was performed during the second trimester that revealed a normal karyotype. Follow-up serial fetal ultrasound examinations demonstrated complete resolution of the neck mass. The infant was born via cesarean section due to breech presentation. Apgar scores were 1 at 1 minute and 6 at 5 minutes. The infant was briefly intubated in the delivery room but extubated prior to transfer to the nursery. Initial physical examination showed a birth weight of 1300 g (third percentile) and head circumference of 27 cm (less than third percentile). She had a flat nasal bridge, micrognathia, mildly redundant nuchal skin, and a high arched palate. She did not cry or suck and was hypotonic. She developed episodes of apnea and mild respiratory distress requiring reintubation by 6 hours of life. Subsequent evaluation included a normal head ultrasound examination, a normal chest roentgenogram, and negative elevations in antibody titers to toxoplasmosis, rubella, cytomegalovirus, or herpes virus. The infant continued to require mechanical ventilation secondary to recurrent apneic episodes and was transferred to our facility for further evaluation at 7 weeks of age.

Physical examination then revealed a weight of 2.3 kg and head circumference of 31.2 cm. She was mildly dysmorphic as detailed above. Her head shape was dolichocephalic, and she remained in an opisthotonic posture with retrocollis. She was alert, with spontaneous eye opening and visual fixation. There was a paucity of spontaneous body

movement with no behavioral manifestations of crying following noxious stimulation. Extraocular movements, fundi, and pupillary light reactions were normal. She manifested a facial diparesis, worse on the left side. There was no suck, gag, or palatal movement. Bilateral vocal cord paralysis was noted by direct laryngoscopy. The tongue displayed hemiatrophy of the left side and abundant fasciculations. She was hypertonic with diffusely brisk deep tendon reflexes. She withdrew from a pinprick to all four extremities. A head CT scan revealed bilateral thalamic calcifications, hypodensities in the parieto-occipital junctions bilaterally, and prominence of the cerebrospinal fluid spaces in the posterior fossa (Figure, bottom). An EEG was mildly abnormal due to increased background discontinuity and excessive temporal sharp transients. She subsequently required a tracheostomy to receive continuous positive-pressure mechanical ventilations and a nasogastric gavage tube for feeding.

COMMENT

There are four principal brain lesions that may occur in premature infants: matrix-zone hemorrhage, periventricular leukomalacia, white-matter gliosis, and necrosis of the thalamus with or without involvement of the basal ganglia and brain stem.^{12,13} The characteristics of brain injury seen in full-term infants include diffuse corticoneuronal injury, parasagittal "watershed" infarctions, and subcortical leukomalacia. The

pathogenesis of these specific varieties of brain injury reflects different patterns of impaired cerebral perfusion with relative involvement or sparing of specific brain regions.¹² This regional disease has characteristic clinical correlates in both the neonatal period and later life.

A review of the literature¹⁴ reveals only eight previous studies concerning 12 infants who had clinical neurologic evidence of brain-stem injury and pathological evidence of mineralization of the thalami (Table). Computed tomographic scan results were available in only four of these, with abnormal findings in two.

Thalamic and brain-stem injury manifest as prominent bulbar dysfunction out of proportion to the patient's impairment of consciousness. Most often recognized are disordered sucking and swallowing, crying, glossoparesis, and oculomotor difficulties. Although mental status may be depressed initially, the abnormal bulbar signs persist despite the return of normal vigilance. Late sequelae include spastic quadriplegia, hypotonia, movement disorders, mental retardation, and seizures. Similar observations were made in our patients. Despite mild requirements for resuscitation at birth, each displayed profound brain-stem dysfunction. Ab-

Summary of Clinicopathological Cases of Infantile Thalamic Calcifications*

Source, y	Patient	Prenatal Birth History	Gestational Age	Apgar Scores, 1 min/5 min	Clinical Examination, Course	Neuroimage	Pathologic Findings
Rosales and Riggs, ¹ 1962	1	Polyhydramnios	Term	NS	Apneic at birth, required intubation; hypotonic with hyperreflexia; no suck or swallow; NG fed; died at 6 mo	ND	Lateral thalamic atrophy with astrocytic glial hyperplasia and "fossilized" neurons
	2	Polyhydramnios	Term	NS	Cried but flaccid tone and no spontaneous movement at birth; developed opisthotonos, seizures, and apnea; no suck or swallow; NG fed; died at 15 mo	ND	Lateral thalamic atrophy with astrocytic glial hyperplasia and "fossilized" neurons
	3	Uncomplicated	Term	NS	Birth history NS; no suck or swallow; NG fed; died at 16 mo	ND	Lateral thalamic atrophy with astrocytic glial hyperplasia and "fossilized" neurons
Norman, ² 1972	1	NS	Term	1/NS	Intubated at birth; NG fed; at 1 mo: poor suck, eyes turned downward; opisthotonic, spastic; developed seizures and died of aspiration pneumonia at 6 wk	ND	Patchy neuronal loss with encrusted neurons and hypertrophied astrocytes in the thalamus and reticular formation of medulla and pons
	2	Maternal salicylate overdose; breech	34 wk	1/NS	Stridor at birth, intubated; comatose with eyes deviated to right; no suck, grasp or Moro's reflex; flaccid and areflexic with ankle clonus; died at 1 wk	ND	Extensive neuronal loss, encrustation of neurons, and hypertrophied astrocytes in thalamus and bilateral reticular formation from rostral medulla to midbrain
	3	Polyhydramnios	34 wk, low forceps	2/NS	Flaccid, stridorous; intubated, fixed and dilated pupils, with clonus of the left leg; died at 8 d	ND	Neuronal loss, encrusted neurons, and pronounced increase of glia bilaterally of reticular formation, entire brain stem, and thalamus
Ambler and O'Neil, ³ 1975	1	Uncomplicated	42 wk	NS	Apneic at birth; developed opisthotonos and hypertonia by 2 h of age; no suck; NG fed; episodic apnea and bradycardia; died at 3 wk	ND	Severe thalamic cell loss and astrogliosis with cytoplasmic calcoppherules
Abuelo et al., ⁴ 1981	1	(Same case as Ambler and O'Neil; see above)					
	2	Uncomplicated	Term	2/8	Rigid with flexed arms and scissoring legs; apnea at 10 d with development of seizures; died at 2 mo	CT scan of head at 10 d and skull roentgenogram were normal	Microgyria with major neuronal loss and gliosis in thalamus and white matter; mineral concretions in the thalamus
Wilson et al., ⁵ 1982	1	Uncomplicated until loss of variability on fetal monitoring; thick meconium	36 wk	6/6	Intubated at birth; pinpoint pupils; no spontaneous eye movements, gag, suck, or grimace; areflexic and flaccid; seizures at 8 h; died at 16 d	CT scan of head at 4 d was normal	Prominent neuronal loss with mineralization and gliosis of thalamus and multiple cranial nerve nuclei

(cont)

sent gag, absent suck, and weak cry in concert with oculomotor abnormalities and hypotonia summarize their characteristic findings. One patient also developed status epilepticus within the first several hours of life, which suggests a

more global hypoxic-ischemic event involving the cortex. Long-term follow-up is available in two of these patients. Each suffers from severe residual neurologic impairment.

The clinical history and time of detec-

tion of thalamic and brain-stem calcification by CT scan may help date the onset of injury. Wilson et al⁵ described an infant with evidence of intrapartum asphyxia whose CT scan at 4 days of life was normal but whose autopsy at 16

	3	Uncomplicated; CS	32 wk	"moribund"	Intubated immediately; died at 3 h	ND	Periventricular leukomalacia with mineralization, neuronal loss, astrocytosis, and gliosis of reticular formation, thalamus, and elsewhere
Parisi et al, ⁶ 1985	1	Arrested premature labor at 32 wk; CS for double-footling breech	36 weeks	4/7	Apneic, hypertonic flexor posture; poor suck and swallow; NG fed; episodic apnea; died at 4 wk	CT scan of head showed bilateral thalamic densities	Symmetrical patchy areas of severe neuronal loss, astrocytosis, and mineralized neurons within the thalamus; gliosis of brain-stem tegmentum
Roland et al, ⁷ 1988	1	Variable decelerations 1 h prior to birth; sustained bradycardia for 15 min prior to midforceps delivery	Term	1/1	Pale, flaccid, and apneic at birth; required intubation and resuscitation; seizures at 1 h; remained comatose with absent oculocephalic responses; no gag or suck; marked facial diplegia, bilateral ptosis, retrognathia, and tongue fasciculations; required gastrostomy; died at 4 mo	CT scan of head at 5 d was normal; CT scan of head at 14 d showed decreased attenuation, basal ganglia; CT scan of head at 30 d showed dilatation of third ventricle, increased attenuation of tissue adjacent to third ventricle, and tissue loss in thalamus/basal ganglia	Extensive neuronal loss and gliosis of thalamus and brain stem; no hypervascularity in thalamus; dead encrusted neurons adjacent to fourth ventricle and throughout both brain stem and thalamus
Present series	1	Polyhydramnios	34 wk	8/8	At birth, hypotonic with decreased spontaneous activity; poor suck and swallow; NG fed; developed opisthotonos and hypertonicity with cortical blindness, recurrent seizures, and severe developmental delay	CT scan of head at 5 d showed bilateral thalamic calcifications	ND
	2	Uncomplicated breech delivery	36 wk	2/5	Apneic and hypotonic at birth; required intubation and resuscitation at birth; developed seizures at 8 h; required NG feedings for continued poor suck and swallow; at 40 mo had microcephaly, quadriplegia, chronic seizure disorder, and severe developmental delay	CT scan of head at 12 d showed calcification of bilateral thalami and upper brain stem	ND
	3	Maternal treatment with sulfasalazine early first trimester; in utero cystic hygroma resolved; CS for breech	33 wk	1/6	Apneic and hypotonic at birth with little spontaneous activity; no suck or swallow; NG fed; developed hypertonicity, tongue atrophy with fasciculations; and facial diplegia; required tracheostomy	CT scan of head at 49 d showed bilateral thalamic calcifications and ischemic changes of parieto-occipital cortices	ND

*NS indicates not stated specifically; NG, nasogastric gavage; ND, not done; CT, computed tomographic; and CS, cesarean section.

days demonstrated mineralization of diencephalic and brain-stem structure. Abuelo et al⁴ described an infant with a normal 5-minute Apgar score with rigidity and scissoring of the legs noted immediately at birth. The CT scan at day 10 of life was normal, but significant neuronal loss with mineral deposition was present in the thalamus at autopsy 2 months later. Roland et al⁷ described an asphyxiated infant born following significant intrapartum distress who was studied serially by head CT scan examinations. On the fifth postnatal day the CT scan was normal, but by the 14th postnatal day there was decreased attenuation of the basal ganglia. On day 30 of life there was increased attenuation noted in these areas on CT scan as well as tissue loss in the thalamus and basal ganglia. Autopsy at 4 months demonstrated gliosis and encrusted neurons in this region without concomitant hypervascularity. These findings prompted the authors to propose that the increased density seen on CT scan likely reflected reactive gliosis rather than capillary proliferation as has been previously suggested.⁹ Their observations suggest that the development of increased attenuation or calcification of the brain stem and diencephalon to a degree that can be identified by CT may take as long as 2 to 4 weeks after the initial insult.

The neuropathologic examination of prenatally acquired brain injury demonstrates many possible abnormalities: astrocytic hypertrophy, microglia and macrophage infiltration, capillary proliferation, ferrugination, and cystic changes.^{13,14} Ferrugination describes the process by which necrotic cells become encrusted by mineral deposits. The intracellular deposit of iron and calcium salts occurs relatively late after cell death. At least 14 days are required before this response will be observed.¹⁴ The observation of brain mineralization demonstrated by CT or by neuropathologic examination are in good agreement and date the lesion as at least 2 weeks old.

In light of these previous studies and ours, we propose that two clinical patterns emerge in infants with thalamic calcification. The first includes those who suffered *prenatal* injury, as evidenced by polyhydramnios, breech presentation, absence of overt labor com-

plications, spasticity at birth, tongue fasciculations, and the very early identification of thalamic calcifications on CT scan. These infants constitute the majority of patients. Their prenatal injury results in profound bulbar impairment, which renders the infant vulnerable for an "acute asphyxia" at birth. This occurs by virtue of an impaired respiratory drive, diminished capacity to protect the airway, and obstructive apnea secondary to weak pharyngeal musculature. Collectively, these may cause low Apgar scores. In the immediate postdelivery period, the classic signs of acute hypoxic-ischemic encephalopathy may then be superimposed producing hypotonia, seizures, pupillary disturbances, and EEG abnormalities. Infants who do not sustain secondary perinatal asphyxia at birth are more likely to demonstrate clinical findings suggestive of a chronic central nervous system injury such as hypertonicity, rigidity, opisthotonos, athetoid movements, or hyperactive gag reflex.¹² Abuelo et al⁴ and Parisi et al⁶ described infants who typify this pattern of symmetrical thalamic calcification. They exhibited spasticity at birth in combination with bulbar dysfunction and had severe bilateral thalamic neuronal loss with mineralization at autopsy. A CT scan revealed thalamic hyperdensities at 5 days of age.⁶ The clinical findings at birth of hypertonicity, contractures, micrognathia, and/or a high-arched palate in combination with significant brain-stem dysfunction suggest in utero injury. The presence of calcifications on CT scan performed near the time of birth confirms the prenatal onset of the lesions.

The second and less common pattern of presentation includes those patients who had an uncomplicated prenatal course but who sustained significant intrapartum difficulties. These infants have had no history of polyhydramnios and do not immediately manifest tongue fasciculations or other findings suggestive of chronic central nervous system injury. They experience late fetal distress and appear acutely asphyxiated at birth. These infants progress through an evolving sequence of clinical manifestations usually seen in severe acute asphyxia. However, as their mental status and activity improve, signs of bulbar dysfunction persist and dominate the clinical picture at first. Early CT scans

do not reveal the thalamic calcifications, although studies performed later do. Our patient 2 conforms to this group of patients. Similarly, Wilson et al⁵ describe a patient who suffered well-documented fetal and intrapartum distress. This infant appeared acutely asphyxiated at birth and had a normal CT scan within the first week of life. However, by 16 days of age, autopsy revealed thalamic mineralization.

Thus, the timing of the CT identification of thalamic calcification taken in context with the physical examination at birth and the clinical evolution thereafter can help determine whether injury was likely to have been sustained prenatally or during the immediate intrapartum period.

The authors thank Linda Cella for typing the manuscript.

Klebsiella pneumoniae Bacteremia in Children

Fifty-Seven Cases in 10 Years

William A. Bonadio, MD

• A review was performed of the 57 cases of *Klebsiella pneumoniae* bacteremia that occurred in children at our institution during a 10-year period. The rate of *K pneumoniae* bacteremia relative to all blood cultures in which bacteria were isolated was 1.1%. Children younger than 12 months of age accounted for 38 cases (67%). There were 8 children (14%) who were afebrile at the time bacteremia was documented; other presenting clinical features were generally indistinguishable from those that characterize pediatric bacteremia of more common causes. Fourteen children (25%) were receiving broad-spectrum parenteral antibiotic therapy at the time bacteremia was documented. In 53 patients (93%), an underlying condition predisposing to opportunistic infection was identified, the most common of which were lesions of the gastrointestinal tract (56%), presence of an indwelling central venous catheter (35%), and neutropenia (25%). *Klebsiella pneumoniae* was a constituent of polymicrobial bacteremia in 15 patients (26%). The overall mortality rate associated with this infection was 20%, with over one half of all deaths occurring in infants who were afebrile at the time bacteremia was documented. *Klebsiella pneumoniae* bacteremia is a relatively uncommon, serious infection that usually occurs in young children with predisposing underlying conditions, and is associated with a significant mortality rate.

(AJDC. 1989;143:1061-1063)

Klebsiella pneumoniae bacteremia is a relatively rare infectious disorder in children. I know of no previous survey that has been performed to characterize cases of pediatric *K pneumoniae* bacteremia.

This study reviewed all cases of pediatric *K pneumoniae* bacteremia that occurred at our institution during a 10-year period to delineate the clinical features characterizing this infectious disorder.

PATIENTS AND METHODS

A review was performed of the medical records of all patients for whom the results of a blood culture were positive for *K pneumoniae* at the Children's Hospital of Wisconsin, Milwaukee, from 1979 to 1988. Nosocomial infection was one that occurred after 3 days of hospitalization.¹ Antibiotic therapy was considered adequate if there was administration of one or more antimicrobial agents with in vitro activity against the corresponding isolate. Deaths were considered to be contributed to by sepsis if they occurred while patients received treatment for bacteremia, unless clear clinical and pathologic data suggested otherwise.

RESULTS

During the study period, bacteria were isolated in a total of 5156 blood cultures; *K pneumoniae* accounted for 60 isolates. In 57 of the 60 cases, the clinical course was consistent with sepsis. Three other cases were considered to be contaminants. In each of these cases, a previously healthy child was discharged after outpatient evaluation for a febrile illness without receiving antibiotic therapy, and no patients required reevaluation within the subsequent 72-hour period.

Of the 57 patients with *K pneumoniae* bacteremia, the range of ages was 2 days to 19 years: 9 patients were younger than 2 months of age, 29 patients were aged 2 to 12 months, 5 patients were aged 12 to 24 months, 6 patients were aged 2 to 5 years, and 8 patients were older than 5 years of age. There were 34 boys and 23 girls. The racial

distribution included 35 whites, 19 blacks, and 3 Hispanics. Bacteremia was classified as a nosocomially acquired infection in 43 patients (16 patients were receiving care in an intensive care unit). At the time bacteremia was documented, 8 patients were afebrile and 2 patients were hypotensive (requiring pressors).

In general, other presenting clinical features associated with *K pneumoniae* bacteremia were similar to those that characterize the more common causes of pediatric bacteremia. Of note was an otherwise healthy patient with asthma and acute bronchospasm who developed fever and roentgenographic evidence of bilateral perihilar pulmonary infiltrates after receiving parenteral corticosteroid medication for 7 days, and had 3 sequential blood cultures performed during a 72-hour period with positive results for *K pneumoniae*.

Broad-spectrum combination parenteral antibiotic therapy was administered at the time nosocomial bacteremia was documented in 14 cases; in 12 of these cases, antibiotic therapy was adequate, and in 2 cases, the isolate was resistant to the regimen used. During the course of their illnesses, 8 patients (all with nosocomial infection) who were receiving adequate antibiotic therapy that included an aminoglycoside to which the organism was susceptible had at least one blood culture obtained subsequent to the initial positive culture with results that were also positive for *K pneumoniae*. In 7 of these cases, patients were receiving chemotherapy for malignancy or were neutropenic. In 15 patients, *K pneumoniae* was a constituent of polymicrobial bacteremia; 8 of these patients had an underlying lesion of the gastrointestinal tract.

In the 57 cases, a total of 112 clinical

entities were identified that were considered predisposing factors to opportunistic infection (Table). Of the 11 patients who died, all had nosocomial bacteremia, 5 had polymicrobial bacteremia (*K pneumoniae* combined with *Citrobacter diversus*, *Escherichia coli* and *Enterobacter cloacae*, *E. cloacae*, enterococcus and *Staphylococcus epidermidis*, *Pseudomonas aeruginosa* and *E. coli*, and *Staphylococcus aureus*), and 6 (all younger than 12 months of age) were afebrile at the time bacteremia was documented. Autopsy was performed in 3 patients, none of which revealed findings consistent with a specific cause of death other than sepsis.

COMMENT

Klebsiella pneumoniae is a gram-negative encapsulated bacillus of the family Enterobacteriaceae, found to colonize the gastrointestinal and respiratory tracts of hospitalized patients.² Invasive infection is usually nosocomially acquired by the compromised host. This organism is one of the most common causes of nosocomial bacteremia in

children,³ and following *E. coli* is the second leading cause of all nosocomial gram-negative infections in both children³ and adults.^{4,6}

I know of no previous survey that has characterized pediatric cases of *K pneumoniae* bacteremia. In this series, the majority of instances of this infection occurred in younger children, with two thirds of the patients younger than 12 months of age. Bacteremia due to this organism was a nosocomially acquired infection in 75% of the cases, similar to the 77%⁴ and 84%⁵ rates of nosocomially acquired *K pneumoniae* bacteremia in adults. Approximately 25% of the children were receiving broad-spectrum antibiotic therapy at the time bacteremia was documented, reinforcing the concept that antimicrobials may exert selective pressure on normal flora that favors colonization with this organism in hospitalized patients.⁷

The overall mortality rate of 20% observed in this series is similar to the 25%⁴ and 16%⁵ mortality rates documented in adults with *K pneumoniae* sepsis. Specifically, we found that afebrile children younger than 12 months of age represented over one half of all deaths. Perhaps the inability to mount a fever by the compromised, young child with systemic infection is an index of inadequate host response and poor prognosis.

Many of the characteristics of children with *K pneumoniae* bacteremia were uniquely different from those described in adult cases. The overall isolation rate of this organism by blood culture was only 1.1% relative to all blood cultures in which bacteria were isolated, less than the 6.6% rate documented in adults.⁴ In 14% of the cases, the patients were afebrile at the time bacteremia was documented. Although this is three times the rate of afebrile adults with *K pneumoniae* bacteremia previously described,⁴ it is consistent with the rate of afebrile children with more common causes of pediatric bacteremia.⁸ Compared with the 22% rate of associated shock described in an adult series,⁴ only 3.5% of the children experienced this complication. This lower rate may, in part, reflect the level of ongoing, in-hospital monitoring taking place for many children known to have serious underlying conditions when bacteremia

developed, prompting early and aggressive treatment.

Almost all instances of *K pneumoniae* bacteremia were associated with at least one underlying condition considered to be a predisposing factor for opportunistic infection. In contrast to adult series in which the urinary, respiratory, and gastrointestinal tracts were the three most common sources of *K pneumoniae* bacteremia,^{4,5} we found that lesions of the gastrointestinal tract (56%), the presence of an indwelling central venous catheter (35%), and neutropenia (25%) were the predominating conditions in children; an underlying lesion of the urinary tract was identified in only 16% of the pediatric cases.

The association of the presence of indwelling central venous catheters with *K pneumoniae* bacteremia has been demonstrated in the adult literature.^{9,10} There was a noted propensity for persistent bacteremia in those patients with underlying immunodeficiency states (neutropenia and chemotherapy administered for malignancy), despite receiving adequate antibiotic therapy. Also of note was an otherwise healthy child with asthma who developed nosocomial pneumonia and persistent *K pneumoniae* bacteremia while receiving corticosteroid medication. Administration of corticosteroids can be a predisposing factor for the development of gram-negative sepsis in certain hosts¹¹; one should be aware of this potential complication, even in otherwise healthy children with asthma when corticosteroid therapy is used.

Klebsiella pneumoniae was a constituent of polymicrobial bacteremia in 26% of the cases, higher than the 12%⁴ and 16%⁵ rates of a polymicrobial cause observed in adult series of gram-negative bacteremia. The most common predisposing factor associated with polymicrobial bacteremia was an underlying lesion of the gastrointestinal tract, a finding similar to that noted in a previous report of pediatric polymicrobial bacteremia of diverse causes.¹² Polymicrobial bacteremia in which *K pneumoniae* was a constituent denoted a poor prognosis, with death occurring in one third of the cases. Yet, this mortality rate does not differ from that previously described in children with polymicrobial bacteremia of diverse causes.^{12,13}

Klebsiella pneumoniae bacteremia is a relatively uncommon but serious pediatric infection that usually occurs in younger children with predisposing underlying conditions. A significant mor-

tality rate is associated with *K pneumoniae* bacteremia, especially in those patients who are afebrile or experience polymicrobial bacteremia. When *K pneumoniae* bacteremia occurs, a thor-

ough investigation should be performed to identify a possible underlying condition predisposing to this opportunistic infection.

Fiberoptic Bronchoscopy in the Treatment of Intubated Neonates

Eric S. Shinwell, LRCP, MRCS; Rosemary D. Higgins, MD; Richard L. Auten, MD; Donald L. Shapiro, MD

• A study of the role of fiberoptic bronchoscopy in intubated neonates was conducted. The study aimed to ascertain the applicability of fiberoptic bronchoscopy for assessment of endotracheal tube tip position, and to assess the incidence and clinical significance of airway disease in unselected patients. Seventy examinations on 65 neonates were performed without interruption of mechanical ventilation. The procedure was well tolerated in all cases. The accuracy of bronchoscopic measurement of endotracheal tube tip position improved markedly with user experience and reached a correlation of .96 with a chest roentgenogram. Although the technique was safe and accurate, the need for available and skilled personnel may limit the applicability of this method for endotracheal tube tip position assessment. Significant airway disease requiring a change in treatment was found in 13 patients (19%). This high incidence of significant but clinically unsuspected airway disease suggests that there should be more frequent consideration of diagnostic bronchoscopy in all sick intubated neonates who are at risk for airway disease.

(AJDC. 1989;143:1064-1065)

The development of ultrathin fiberoptic bronchoscopes has made routine bronchoscopic examination of the neonatal airway a practical possibility. Although the available instruments are limited by a lack of distal angulation and by reduced image resolution, they offer the potential for routine bedside examination of sick intubated neonates.

Vigneswaran and Whitfield¹ studied the use of a 1.8-mm fiberoptic bronchoscope (Olympus, Columbia, Md) for confirmation of endotracheal tube

(ETT) position in 20 intubated infants. They reported that the procedure was accurate and safe, noting only a small drop in transcutaneous PO_2 associated with both bronchoscopy and chest roentgenography. Airway disease was not reported in these neonates. Wood and Postma² and Wood³ described an extensive experience with bronchoscopic examination of neonates for specific indications, such as airway stenosis, plugging or compression, stridor, atelectasis, and difficult intubation. The ultrathin bronchoscope was found to have limited application because of the lack of distal angulation and occasional difficulty in identifying the carina with certainty. This problem was partially overcome in this study by alteration of head position combined with swiveling of the bronchoscope about its long axis; the slight angulation present in the bronchoscope facilitated directions into each of the major bronchi. Fan et al⁴ have described extensive experience with a 2.7-mm bronchoscope (Olympus), mostly in older infants. This instrument has the advantage of a directable tip but is limited by the absence of a suction channel. In addition, it will not pass an ETT smaller than 3.5 mm.

Thus, this study was conducted to assess the safety, accuracy, and applicability of fiberoptic bronchoscopy for routine determination of ETT position and for assessment of airway disease in an unselected group of sick intubated neonates.

METHODS

This study was approved by the Human Investigation Committee of the University of Rochester (NY) Medical Center. Neonates studied had been intubated or reintubated within the preceding hour, and each underwent both chest roentgenography and fiberoptic bronchoscopy. Neonates were selected at random for study when a bronchos-

copist was available. The ETT-carina distance on the roentgenogram was independently read by the neonatologist or neonatology fellow on call.

Bronchoscopy was performed by one of three individuals (E.S.S., R.D.H., or R.L.A.). The bronchoscopes (Visicath, Microvasive, Milford, Mass) employed were either 1.3 or 2.0 mm in external diameter, depending on the size of the neonate. The 2-mm bronchoscope has 0.4- and 0.9-mm channels: the 0.4-mm channel was used for oxygen, lavage, or clearing the viewing screen, and the 0.9-mm channel was used for suctioning, usually requiring relatively high negative pressure. The bronchoscope was introduced into the ETT via an elbow connector (Baxter-Airlife, McGaw Park, Ill), which was specially adapted with a small hole to accommodate the bronchoscope and thus allow for uninterrupted mechanical ventilation. The bronchoscope was advanced to the carina; the bronchoscopist placed a finger at the entry of the scope into the ventilator system and pulled back until the ETT tip came into view. The distance was measured and recorded. If the ETT was in the right main bronchus, this was diagnosed by the nature of bifurcation seen, and the ETT was then pulled back under direct vision until the carina was seen. The procedure was always performed with the head positioned as for the chest roentgenogram. A survey of the trachea and major bronchi to the lower lobe bifurcations was performed, and abnormalities were noted. As the bronchoscopes have no distal angulation, entry into the major bronchi was obtained by manipulation of the infant's head and swiveling the bronchoscope about its long axis. This was usually accomplished without difficulty, although this skill did appear to improve with investigator experience. During the procedure, the infant's condition was followed with pulse oximetry or transcutaneous oxygen monitoring. No changes were made in the infant's ventilator settings or oxygen flow during the procedure.

Statistical analysis included correlation coefficients and analysis of significance of bronchoscopic and roentgenographic measurements.

Reprints not available.

Correlation coefficients between bronchoscopic and roentgenographic measurements. Data are summarized for seven groups of 10 examinations each.

RESULTS

Seventy examinations were performed on 65 neonates. Mean gestational age was 32 weeks (range, 24 to 42 weeks), and mean weight at time of examination was 1610 ± 1054 g (range, 540 to 4400 g). Age at time of examination ranged from 30 minutes to 6 weeks.

During the procedure, no ETTs were dislodged. No significant changes were noted in oxygen saturation as measured by pulse oximetry or arterial blood gases. No change in ventilator settings was required after the procedure.

The correlation coefficient between the bronchoscopic and roentgenographic measurements rose from .26 in the first group of 10 examinations to .96 in the final group of 10. The Figure shows the correlation coefficients for sequential examinations; the slope of the graph represents the "learning curve." These data represent the combined experience of three investigators, each of whom performed approximately one third of the studies. The learning curve for each of the investigators was similar and, thus, an individual investigator should achieve a correlation of .95 or greater after approximately 20 studies.

Abnormal airway findings of clinical significance that had not been suspected prior to examination were found in 13 examinations (19%). Clinical significance was defined as findings that altered the patient's management, and these included such diagnoses as

tracheobronchomalacia in two term neonates, necrotizing tracheobronchitis in one extremely premature neonate, plugging of major airways with meconium and with mucus in two neonates each, and early hemorrhagic pulmonary edema in two neonates. Frothy hemorrhagic secretions were noted in the airways in these cases long before they were seen in or suctioned from the ETT. Additional problems that related to ETT position included positioning above a stenotic region in one neonate, occlusion of the ETT orifice by the lateral tracheal wall in two neonates, and ruling out of suspected ETT occlusion in one neonate. Examples of the changes in clinical management included dislodging and suctioning meconium and mucus plugs with the bronchoscope, alteration of ventilation strategy and extreme care to suction only to the end of the ETT in the neonate with necrotizing tracheobronchitis, and the use of increased positive end-expiratory pressure in hemorrhagic pulmonary edema. The results of these interventions produced a dramatic improvement in the ventilatory status of one of the neonates with meconium plugging; more moderate improvements were seen in the other neonates with plugged airways, with gradual improvement in the condition of the neonate with necrotizing tracheobronchitis and prompt resolution of the hemorrhagic pulmonary edema.

COMMENT

This study demonstrates that fiberoptic bronchoscopy is a safe and accurate method for assessment of ETT position and has utility for the detection of significant airway disease that is unsuspected on clinical grounds. Some problems were encountered in the use of the bronchoscope, including difficulty directing the bronchoscope consistently and easily to the desired bronchus, a tendency for blurring of the screen with secretions, and inability to examine the upper lobe bronchi. One error in the early phase of the study was misdiagnosis of the bifurcation of the right main

ductus bronchus for the main carina. No difference in incidence of problems was noted between the two bronchoscopes used.

Although the procedure is relatively rapid (30 to 60 seconds per examination), it demands skilled personnel who may not be available in all neonatal intensive care unit settings. This fact, combined with the relative ease of acquiring a chest roentgenogram, may limit the widespread applicability of this procedure for assessing ETT placement. However, this method could potentially save many neonates from unnecessary repeated roentgen ray exposure.

It is striking that such a high incidence of clinically significant airway problems was found. To our knowledge, there are no reported studies of the prospective use of routine bedside bronchoscopy in all intubated neonates; such a study would appear to be indicated by the above data.

In summary, ultrathin fiberoptic bronchoscopy was found to be a useful diagnostic and therapeutic tool in the intubated neonate. Endotracheal tube position can be reliably confirmed by this method. An important application of bronchoscopy may be for screening for airway disease in intubated neonates.

This work was supported by grant HL-36543 from the National Heart, Lung, and Blood Institute, Bethesda, Md, and by a grant from Strong Memorial Hospital (Rochester, NY) Innovations in Patient Care Program.

Infant Sleep and Bedtime Cereal

Michael L. Macknin, MD; Sharon VanderBrug Medendorp, MPH; Mary C. Maier, MD

• We studied whether feeding infants rice cereal before bedtime promotes their sleeping through the night. One hundred six infants were randomly assigned to begin bedtime cereal feeding (1 tablespoon per ounce in a bottle) at 5 weeks or at 4 months of age. Caretakers recorded the infant's sleep from age 4 to 21 weeks for the 24-hour period per week. Sleeping through the night was defined as sleeping at least 8 consecutive hours, with the majority of time being between the hours of midnight and 6 AM. The results were also reviewed changing the requirement from 10 hours to 6 hours. There was no statistically significant trend or a consistent tendency of one group to have a higher proportion of sleepers than the other. Therefore, feeding infants rice cereal in the bottle before bedtime does not appear to make much difference in their sleeping through the night.

(AJDC. 1989;143:1066-1068)

Folklore suggests that feeding infants solids prior to bedtime increases the duration of uninterrupted sleep. This is somewhat documented in the literature. In a survey of Nebraskan pediatricians and family practitioners, 40% of the respondents agreed that "one advantage of adding solid food to the diet very early is that it helps baby sleep through the night."¹ Several poorly controlled, unrandomized studies suggest that feeding infants solids helps them to sleep through the night.²⁻⁴ Clinical practice shows that many parents use this reasoning to introduce multiple solid foods to infants in the first few months of life.

There is also evidence to suggest that

feeding of solids prior to bedtime is not related to evening sleep patterns. Recently, an abstract of a randomized controlled clinical trial reported that cereal given before bedtime will not help an infant sleep through the night.⁵ Many poorly controlled, unrandomized studies suggest that the introduction of solid food has no relationship to sleeping through the night.⁶⁻¹¹

The American Academy of Pediatrics Committee on Nutrition suggests that for theoretical reasons the introduction of solid foods should be delayed until an infant is 4 to 6 months old.¹² The theoretical reasons for withholding solid foods until this time include decreasing solute load placed on an immature kidney, avoiding overfeeding and force-feeding, and preventing allergic reaction secondary to immature antigen processing. There are no proved adverse effects of early introduction of cereal into an infant diet.¹³ This study was designed to determine if infant rice cereal given before bedtime will help an infant sleep through the night.

SUBJECTS AND METHODS

Subjects

One hundred six newborns who had a birth weight of over 2.5 kg and were first seen for well-child care at The Cleveland (Ohio) Clinic Foundation Pediatric Primary Care Center before the age of 1 month were eligible for study. Four additional subjects enrolled in the study could not be included in the data analyses because their parents did not complete any cry/fuss diaries. The Pediatric Primary Care Center provides health care to the children of employees of The Cleveland Clinic Foundation. Children were ineligible for study if they were without a consistent caretaker after 6 PM or had congenital anomalies or other illnesses that might significantly impair feeding.

Procedures

At either a prenatal or first well-child visit before the age of 1 month, parents were asked to give verbal informed consent for

participation in a study of infant sleeping patterns. Children were randomly assigned to begin bedtime cereal feeding at 5 weeks of age (early group) or 4 months of age (late group). The parents in both groups were asked to feed their infants only rice cereal, breast milk, and/or formula until 5 months of age.

Beginning at 1 month of age, parents in both groups recorded their infant's periods of crying and fussing each week from noon Tuesday through noon Wednesday on the parental diary of infant behavior devised by Barr et al,¹⁴ an instrument previously validated by 24-hour cry/fuss recordings. They were also asked to record periods of sleeping and quantity or length of feedings in bottle-fed and breast-fed infants. Infants received cereal-thickened feedings, one tablespoon per ounce of breast milk or formula, from a bottle between 6 PM and 9 PM only. The amount of cereal was recorded. At 4 months of age, infants in the second group had rice cereal introduced into their diets in an identical manner. (Note that we do not routinely recommend feeding infants cereal in a bottle. However, we did not want to introduce infant reaction to spoon-feeding as an additional variable in the study.) Both groups of parents continued to record infant cry/fuss, feeding, and sleeping patterns until 5 months of age.

The sample size was chosen to detect a success rate of 25% vs 50% at a significance level of 5%, with 80% power, assuming a 20% noncompletion rate of the study.¹⁵ Success was defined as an infant sleeping 8 consecutive hours, with the majority of the sleeping between midnight and 6 AM.

Randomization of subjects to the two feeding schedules was balanced after every fourth patient in each of the assignment risk strata. Randomization was accomplished by sealed envelopes generated for each risk stratum by the Department of Biostatistics and Epidemiology. The strata were defined by birth weight (2.50 to 3.00 kg, 3.01 to 3.50 kg, 3.51 to 4.00 kg, 4.01 kg or more) and a mother's intention to primarily breast-feed or bottle-feed. Additional variables not included in the randomization were maternal and paternal education (in years), race, number of other children less than 5 years old in the household, household member working

Fig 1.—Proportion of infants sleeping at least 6 consecutive hours, with the majority of the time between midnight and 6 AM. Early cereal represents the group given cereal at 5 weeks of age; late cereal, the group given cereal at 4 months of age.

Fig 2.—Proportion of infants sleeping at least 8 consecutive hours, with the majority of the time between midnight and 6 AM. Early cereal represents the group given cereal at 5 weeks of age; late cereal, the group given cereal at 4 months of age.

an evening shift, amount of cereal eaten in 24 hours, weight for height percentile, amount of formula consumed per 24 hours, number of feedings per 24 hours, number of cry/fuss periods per 24 hours, and weight percentile.

The major analysis consisted of a comparison of the proportions of subjects sleeping through the night in the two groups. This comparison was reported specifically when the participants were 4, 8, 12, 16, and 20 weeks of age. These weeks were chosen because they represent roughly the first 5 months of an infant's life and because there were no dramatic week-to-week variations in sleep data. (Weekly data are available on request.)

The χ^2 and Student's *t* tests were used to explore whether the prognostic risk factors (birth weight, type of feeding, maternal education level, etc) were in fact associated with evening sleeping at various times/ages throughout the study period.¹⁶

RESULTS

At baseline (4 weeks of age), the two feeding groups were comparable in parent's intention to primarily breast-feed or bottle-feed (52.7% intended to breast-feed in the early group, 54.9% in the late group). They also had comparable birth weights, maternal and paternal levels of education, number of children under 5 years of age in the household, household members working an evening shift, sex, race, and baseline sleeping patterns.

The data were analyzed for a sleep requirement of both 8 and 6 consecutive hours. Sleeping through the night for both the 8- and 6-hour definitions was

unrelated at weeks 4, 8, 12, 16, and 20 to the level of parental education, number of children in the household less than 5 years of age, household members working an evening shift, breast-feeding versus bottle-feeding, birth weight, gender, and race. Infant sleep patterns were unrelated to the introduction of bedtime cereal in the bottle.

The mean total sleep was 13.8 and 14.2 hours for the early and late groups, respectively, at 4 weeks of age, and 13.8 hours for both groups at 20 weeks of age. The means varied little during the time of the study (13.3 to 14.4 hours in the early group, 13.4 to 14.2 hours in the late group).

The total mean number of sleeping periods diminished in a similar manner in both the early and late groups, respectively (7.2 and 7.4 at 4 weeks, 6.2 and 6.3 at 8 weeks, 5.0 and 5.7 at 12 weeks, 5.2 and 5.0 at 16 weeks, and 4.5 and 5.3 at 20 weeks).

The lengths of the first, second, and third longest duration of sleep were compared for the two groups. At 4 weeks of age, the mean longest durations of sleep for the early and late groups were 4.6 and 5.2 hours, respectively; this increased to 7.1 and 7.0 hours, respectively, at 8 weeks; 8.5 and 8.3 hours, respectively, at 12 weeks; 8.3 and 8.8 hours, respectively, at 16 weeks; and 8.9 and 8.6 hours, respectively, at 20 weeks. Note that while there is a steady increase in the duration of sleep with age, there is no clear difference in sleep duration between the two

groups at any of the time points.

For recording purposes, the 24-hour clock was divided into four 6-hour segments: noon to 6 PM, 6 PM to midnight, midnight to 6 AM, and 6 AM to noon. Along with the length of the longest duration of sleep, the time of day during which the majority of this period occurred was also recorded. In both groups the longest sleep period occurred most often in the midnight to 6 AM time slot. This was true throughout the study period. At 4, 12, and 20 weeks, 69.0%, 71.1%, and 86.2%, respectively, in the early cereal group and 70.4%, 69.0%, and 71.9%, respectively, in the late cereal group experienced the longest sleep duration between midnight and 6 AM.

The proportion of infants sleeping at least 6 consecutive hours was 16.7% and 20.5% in the early and late groups, respectively, at 4 weeks of age; 56.3% and 37.2%, respectively, at 8 weeks of age; 60.5% and 57.1%, respectively, at 12 weeks of age; 56.4% and 58.8%, respectively, at 16 weeks of age; and 72.4% and 62.5%, respectively, at 20 weeks of age (Fig 1).

When the requirement was increased from 6 to 8 consecutive hours of sleep, the proportions at 4 weeks (Fig 2) were 2.4% and 13.6% in the early and late groups, respectively. With the introduction of bedtime cereal at 5 weeks, 2.0% of the early cereal group and 8.7% of the late cereal group met the criteria. At 8 weeks, the criteria were met by 22.9% and 25.6% of the infants; at 12 weeks, 50.0% and 38.1% of the infants; at 16 weeks, 46.2% and 47.1% of the infants; and at 20 weeks, 51.7% and 56.3% of the infants in the early and late cereal groups, respectively. Although the proportion increased with age, there were no statistically significant differences for either definition in the proportion of infants sleeping through the night between the early and late cereal groups during any week studied from age 4 to 21 weeks, except at age 7 weeks for the 8-hour definition. At age 7 weeks, 27.9% of the late-feeding group and 8.5% of the early-feeding group ($P < .05$) slept through the night. Since this difference at 7 weeks of age was not part of a trend or consistent tendency it must be reviewed and interpreted in this context.

COMMENT

Our findings support previous studies suggesting that infants' ability to sleep through the night is a developmental and adaptive process that occurs regardless of the timing of introduction of cereal.^{7,8}

Several uncontrolled unrandomized studies have been done to study infant sleep patterns.^{4-10,17} Data recorded in previous studies of infant sleep patterns have primarily been done with unvalidated instruments, with the exception of Kleitman and Engelmann's¹⁸ use of actogram recorders on cribs of infants. Parmelee et al⁷ studied 46 infants during the first 16 weeks of life and found that a diurnal cycle was evident in the first 2 weeks of life, becoming statistically significant by 8 weeks of age. Solid foods were introduced in an uncontrolled manner, and the time of their introduction was found not to correlate with increased sleeping times. These findings are consistent with our own. Beal⁸ states that of infants fed solids in the first 4 weeks of life, 28% were already sleeping through one night feeding prior to the introduction of solid foods. She believes that the ability to sleep through the night is a stage reached in the second month of life regardless of diet composition. Other articles support these findings.^{6,7,9,10}

There are several uncontrolled, anecdotal studies supporting the introduction of solid foods to help infants sleep through the night. These include a study by Glazier² who felt that infants fed solids had "fewer faulty habits, including sleeping difficulties." Sackett³ designed a three-meal-a-day plan eliminating nighttime feedings. Wilkinson and Davies⁴ claimed to reach higher levels of contentment among infants receiving solid foods.

Previous studies have also compared sleeping patterns among breast-fed and bottle-fed infants.¹⁸ The breast-fed infants continued to have frequent nighttime wakings and fewer total hours of sleep per day during the first 2 years of life. This has also been noted by Keane et al.⁵ In our study the infants were classified at the time of enrollment into breast-feeding or bottle-feeding groups based on the mother's intention. The data based on this intention did not support a difference in sleeping patterns for breast-fed and bottle-fed infants. This lack of difference may have been due to a difference in definitions of a breast-fed or bottle-fed infant. Perhaps enough mothers changed their predominant feeding method during the study to obscure differences in sleeping patterns between the two groups. Also, the specific method of breast-feeding, tradi-

tional (every 2 to 4 hours) vs LeLeche (every 1 hour or on demand) was not controlled for. The timing of feedings was left to the mother's discretion. There was less variability for all infants in total time slept per day and in what segment of the day the longest sleep period occurred as the infants matured, whether they were fed cereal early or late, and whether they were breast-fed or bottle-fed.

The majority of infants in our study slept 6 consecutive hours at night by 12 weeks of age and 8 consecutive hours at night by 20 weeks of age. The timing of the introduction of cereal in the bedtime bottle was not related to total hours of sleep, number of sleeping periods, longest duration of sleep, or the time interval in which sleep occurred. In addition, no relationship was found between sleeping through the night and introduction of cereal at 5 weeks vs 4 months of age. The results of our study refute the practice of introducing bedtime cereal in an infant's bottle to promote sleeping through the night.

We thank Ruth Imrie, MD, Dan Shapiro, MD, Diana Wasikowski, RN, and the Pediatric Primary Care nurses for help in recruiting patients for this study, and Ms Shelley Gabor for expert secretarial assistance.

They trust you to recommend what's best for them.

LIQUIPRIN has earned the confidence of parents and pediatricians with dependable relief of fever and pain for over 25 years.

The LIQUIPRIN acetaminophen formula does not contain aspirin or alcohol and has a pleasant-tasting fruit flavor that babies like.

The LIQUIPRIN advanced dropper system has a larger tube and bulb, making each dose easier to measure. The bottle is unbreakable plastic with a safety-sealed, child-proof cap. And LIQUIPRIN is priced well below Tylenol.[®]

LIQUIPRIN. Pediatricians recommend it over 1½ million times a year. For good reason.

Available as an Elixir, too.

BUILDING BLOCKS FOR CHILDREN'S HEALTH

Connaught DTP Vaccine

(Diphtheria and Tetanus Toxoids and Pertussis Vaccine, Adsorbed, USP)

Dedicated to the research, development, manufacture and distribution of vaccines and biologicals, Connaught Laboratories ensures a consistently high level of product quality and purity while maintaining a competitive price in the marketplace. Connaught DTP Vaccine — quality built upon product and service.

ALSO AVAILABLE:

Diphtheria and Tetanus Toxoids Adsorbed USP (DT)

Connaught DTP Vaccine

(Diphtheria and Tetanus Toxoids and Pertussis Vaccine, Adsorbed, USP)

BRIEF SUMMARY

Before prescribing, please consult the complete package circular.

INDICATIONS AND USAGE: For active immunization of infants and children to age 7 years against diphtheria, tetanus and pertussis (whooping cough) simultaneously. DTP is recommended for primary immunization of infants and children up to 7 years of age. However, in instances where the pertussis vaccine component is contraindicated, or where the physician decides that pertussis vaccine is not to be administered, Diphtheria and Tetanus Toxoids Adsorbed (For Pediatric Use) should be used. Immunization should be started at 6 weeks to 2 months of age and be completed before the seventh birthday.

CONTRAINDICATIONS: Persons 7 years of age and older must NOT be immunized with Pertussis vaccine.

Absolute contraindications.

1. Allergic hypersensitivity to any component of the vaccine.
2. Fever of 40.5°C (105°F) or greater within 48 hours.
3. Collapse or shock-like state (hypotonic-hyporesponsive episode) within 48 hours.
4. Persisting, inconsolable crying lasting 3 hours or more or an unusual, high-pitched cry occurring within 48 hours.
5. Convulsion(s) with or without fever occurring within 7 days.
6. Encephalopathy occurring within 7 days; this includes severe alterations in consciousness with generalized or focal neurologic signs.

The presence of a neurologic condition characterized by changing developmental or neurologic findings, regardless of whether a definitive diagnosis has been made, is also considered an absolute contraindication to receipt of pertussis vaccine, because administration of DTP may coincide with or possibly even aggravate manifestations of the disease. Such disorders include uncontrolled epilepsy, infantile spasms, and progressive encephalopathy.

Use of this product is also contraindicated if the child has a personal or family history of a seizure disorder. However, the ACIP does not accept family histories of convulsions or other central nervous system disorders as contraindications to pertussis vaccination.

IT IS ALSO A CONTRAINDICATION TO ADMINISTER DTP TO INDIVIDUALS KNOWN TO BE SENSITIVE TO THIMEROSAL. IN ANY CASE, EPINEPHRINE INJECTION (1:1000) MUST BE IMMEDIATELY AVAILABLE SHOULD AN ACUTE ANAPHYLACTIC REACTION OCCUR DUE TO ANY COMPONENT OF THE VACCINE.

Elective immunization procedures should be deferred during an outbreak of poliomyelitis.

WARNINGS: This vaccine must NOT be used for immunizing persons 7 years of age and older.

IMMUNIZATION SHOULD BE DEFERRED DURING THE COURSE OF ANY ACUTE ILLNESS. THE OCCURRENCE OF ANY TYPE OF NEUROLOGICAL SYMPTOMS OR SIGNS, INCLUDING ONE OR MORE CONVULSIONS (SEIZURES) FOLLOWING ADMINISTRATION OF THIS PRODUCT IS AN ABSOLUTE CONTRAINDICATION TO FURTHER USE. USE OF THIS PRODUCT IS ALSO CONTRAINDICATED IF THE CHILD HAS A PERSONAL OR FAMILY HISTORY OF A SEIZURE DISORDER.

THE PRESENCE OF ANY EVOLVING OR CHANGING DISORDER AFFECTING THE CENTRAL NERVOUS SYSTEM IS A CONTRAINDICATION TO ADMINISTRATION OF DTP REGARDLESS OF WHETHER THE SUSPECTED NEUROLOGICAL DISORDER IS ASSOCIATED WITH OCCURRENCE OF SEIZURE ACTIVITY OF ANY TYPE.

The administration of DTP to children with proven or suspected underlying neurological disorders, must be decided on an individual basis. Please refer to ACIP recommendations for the following categories of patients:

1. Infants as yet unimmunized who are suspected of having underlying neurologic disease.
2. Infants and children with neurologic events temporally associated with DTP.
3. Incompletely immunized children with neurologic events occurring between doses.
4. Infants and children with stable neurologic conditions.
5. Children with resolved or corrected neurologic disorders.

Immunosuppressive therapies, including irradiation, antimetabolites, alkylating agents, cytotoxic drugs, and corticosteroids (used in greater than physiologic doses), may reduce the immune response to vaccines. Short-term (less than 2 weeks) corticosteroid therapy or intra-articular, intra-ocular, or tendon injections with corticosteroids should not be immunosuppressive. Although no specific studies with pertussis vaccine are available, if immunosuppressive therapy will be discontinued shortly, it would be reasonable to defer immunization until the patient has been off therapy for one month; otherwise, the patient should be vaccinated while still on therapy.

Persons receiving immunosuppressive therapy, a recent injection of immune globulin, or having an immunodeficiency disorder, may not generate an adequate immunologic response to the DTP vaccine.

DTP should not be given to infants or children with any coagulation disorder that would contraindicate intramuscular injection, unless the potential benefit clearly outweighs the risk of administration.

The simultaneous administration of DTP, oral polio virus vaccine (OPV), and/or measles-mumps-rubella vaccine (MMR) has resulted in seroconversion rates and rates of side effects similar to those observed when the vaccines are administered separately. Please refer to ACIP recommendations.

PRECAUTIONS

GENERAL

Epinephrine injection (1:1000) must be immediately available should an acute anaphylactic reaction occur due to any component of the vaccine.

Prior to an injection of any vaccine, all known precautions should be taken to prevent side reactions. This includes a review of the patient's history with respect to possible sensitivity and any previous adverse reactions to the vaccine or similar vaccines (see CONTRAINDICATIONS), and a current knowledge of the literature concerning the use of the vaccine under consideration.

The vial of vaccine should be vigorously shaken to ensure a proper suspension of the antigen and adjuvant.

Special care should be taken to ensure that the injection does not enter a blood vessel.

A separate sterile syringe and needle or a sterile disposable unit should be used for each individual patient to prevent transmission of hepatitis or other infectious agents from one person to another.

ADVERSE REACTIONS

Not all adverse events following administration of DTP are causally related to DTP vaccine.

Adverse reactions which may be local and include pain, erythema, heat, edema and induration with or without tenderness, are common after the administration of vaccines containing diphtheria, tetanus, or pertussis antigens. Some data suggest that febrile reactions are more likely to occur in those who have experienced such responses after prior doses. However, these observations were not noted by Barkin, R.M., et al. Occasionally, a nodule may be palpable at the injection site of adsorbed products for several weeks. Sterile abscesses at the site of injection have been reported (6-10 per million doses).

Mild systemic reactions, such as fever, drowsiness, fretfulness, and anorexia, occur quite frequently. These reactions are significantly more common following DTP than following DT, are usually self-limited, and need no therapy other than, perhaps, symptomatic treatment (e.g., antipyretics). Rash, allergic reactions, and respiratory difficulties, including apnea, have been observed.

Moderate to severe systemic events, such as fever of 40.5°C (105°F) or higher, persistent, inconsolable crying lasting 3 hours or more, unusual high-pitched crying, collapse, or convulsions, occur relatively infrequently. More severe neurologic complications, such as a prolonged convulsion or an encephalopathy, occasionally fatal, have been reported to be associated with DTP administration.

Approximate rates for adverse events following receipt of DTP vaccine (regardless of dose number in the series) are indicated in Table 1.

TABLE 1. Adverse events occurring within 48 hours of DTP immunizations

Event	Frequency*
Local	
Redness	1/3 doses
Swelling	2/5 doses
Pain	1/2 doses
Mild/moderate systemic	
Fever >38°C (100.4°F)	1/2 doses
Drowsiness	1/3 doses
Fretfulness	1/2 doses
Vomiting	1/15 doses
Anorexia	1/5 doses
More serious systemic	
Persistent, inconsolable crying (duration ≥3 hours)	1/100 doses
High-pitched, unusual cry	1/900 doses
Fever ≥40.5°C (≥105°F)	1/330 doses
Collapse (hypotonic-hyporesponsive episode)	1/1,750 doses
Convulsions (with or without fever)	1/1,750 doses
Acute encephalopathy†	1/110,000 doses
Permanent neurologic deficit†	1/310,000 doses

*Number of adverse events per total number of doses regardless of dose number in DTP series.

†Occurring within 7 days of DTP immunization.

The frequency of local reactions and fever following DTP vaccination is significantly higher with increasing numbers of doses of DTP, while other mild to moderate systemic reactions (e.g., fretfulness, vomiting) are significantly less frequent. If local redness of 2.5 cm or greater occurs, the likelihood of recurrence after another DTP dose increases significantly.

Although there are uncertainties in the reported studies, recent data suggest that infants and young children who have had previous convulsions (whether febrile or nonfebrile) are more likely to have seizures following DTP than those without such histories.

Rarely, an anaphylactic reaction (i.e., hives, swelling of the mouth, difficulty breathing, hypotension, or shock) has been reported after receiving preparations containing diphtheria, tetanus, and/or pertussis antigens.

Sudden infant death syndrome (SIDS) has occurred in infants following administration of DTP. A large case-control study of SIDS in the United States showed that receipt of DTP was not causally related to SIDS. It should be recognized that the first three primary immunizing doses of DTP are usually administered to infants 2-6 months old and that approximately 85% of SIDS cases occur at ages 1-6 months, with the peak incidence occurring at 6 weeks-4 months of age. By chance alone, some SIDS victims can be expected to have recently received vaccine.

Onset of infantile spasms has occurred in infants who have recently received DTP or DT. Analysis of data from the NCS on children with infantile spasms showed that receipt of DTP or DT was not causally related to infantile spasms. The incidence of onset of infantile spasms increases at 3-9 months of age, the time period in which the second and third doses of DTP are generally given. Therefore, some cases of infantile spasms can be expected to be related by chance alone to recent receipt of DTP.

Reporting of Adverse Events

Reporting by parents and patients of all adverse events occurring within 4 weeks of antigen administration should be encouraged.

The following illnesses have been reported as temporally associated with the vaccine; neurological complications including cochlear lesion, brachial plexus neuropathies, paralysis of the radial nerve, paralysis of the recurrent nerve, accommodation paresis, and EEG disturbances with encephalopathy. In the differential diagnosis of polyradiculoneuropathies following administration of a vaccine containing tetanus toxoid, tetanus toxoid should be considered as a possible etiology.

Educational Interventions

Hugh D. Allen, MD, Columbus, Ohio
Fredric Burg, MD, Philadelphia, Pa
Harold Levine, MPA, Galveston, Tex
Barbara Starfield, MD, Baltimore, Md
Larrie W. Greenberg, MD, Washington, DC

Purpose.—This department is intended to share information concerning educational efforts in the broad field of pediatrics. We welcome studies on the following topics: undergraduate and graduate education in medicine and allied health occupations; continuing education of health professionals; education of patients and families; and health education for the general public, the community, and organizations that contribute to the promotion and improvement of the health of children.

Editorial Comment.—*This article advocates a careful, prospectively planned approach to curriculum development and its evaluation. The authors applied their approach to an important topic that involves pediatrics and medicine. This is how medical educational research should be done.*—H.D.A.

A Sexually Transmitted Diseases Curriculum in Adolescent Medicine

Jennifer Johnson, MD; J. Dennis Fortenberry, MD; Efstratios Demetriou, MD;
Jana Gober Zimmerman, MS; Robert F. Hill, PhD; Philip J. Rettig, MD

• We conducted a needs assessment and developed and evaluated a model curriculum on sexually transmitted diseases (STDs) for house officers on an adolescent medicine rotation. Residents thought it important for physicians to acquire skill in treating STDs during residency (mean rating, 4.4 on a five-point scale) and were willing to provide medical care for adolescents likely to have an STD (mean rating, 4.4). Knowledge was measured before and after presentation of both of the two curriculum levels. There were significant increases in knowledge after each level, with a mean increase of 4.4 (of 50 possible) points for level 1 and a mean increase of 1.8 (of 38 possible) points for level 2. This improved knowledge about STDs should reflect increased competence and enhanced willingness to treat STDs in adolescents.

(AJDC. 1989;143:1073-1076)

Sexually transmitted diseases (STDs) contribute substantially to adolescent morbidity; the highest rates of many STDs are found in sexually active 15- to 19-year-olds.¹ From 3% to 27% of adolescent females have cervical *Chlamydia trachomatis* infections^{2,3}; 7% to 10% are infected with *Neisseria gonorrhoeae*.^{4,5} Even in an adolescent clinic with a low prevalence of gonorrhea (<1% of cultures positive), STDs were an identified patient concern in 10% of all visits.⁶ Thus, physicians who provide medical care for adolescents should be educated about STDs; however, formal training in diagnosis and management of STDs is offered in only a few medical schools and residency programs.⁷ Only 18% of respondents to a 1980 survey on clinical training in venereology in US and Canadian medical schools rated

their program as adequate.⁷ Only 1 of 117 pediatric programs surveyed in 1980 offered formal training in STDs to house staff; 23% of internal medicine residency programs did so.⁷ A survey conducted in 1983 revealed that a majority of pediatric program graduates expressed satisfaction with residency lectures and training about STDs. However, 14% of these graduates had never diagnosed or treated gonorrhea, and only 13% had done so more than 20 times.

More than half of pediatric residency programs incorporate a training experience in adolescent medicine.⁸ Although the adolescent medicine rotation provides an excellent opportunity for training physicians to diagnose and treat STDs, to our knowledge there have been no reports of formal STD programs within this setting. We describe the development and implementation of a model STD curriculum for house staff participating in an adolescent medicine rotation.

METHODS

Adolescent Medicine Rotation

House staff from the departments of pediatrics and medicine at the University of Okla-

Accepted for publication March 3, 1989.

homa Health Sciences Center, Oklahoma City, participate in 1-month rotations on the adolescent medicine service at Oklahoma Children's Memorial Hospital. Each pediatric house officer rotates on the service annually. Medicine house staff rotate twice on adolescent medicine during their 3 years of residency. During any given month, 7 to 10 house officers are assigned to the adolescent medicine service. Approximately 55 pediatric residents and 45 residents in internal medicine serve in the program annually.

During the rotation, residents have primary responsibility for patients 14 to 21 years of age, including ambulatory patients presenting to the adolescent clinic or the emergency department, and all nonsurgical adolescent inpatients. Each year there are approximately 12 000 outpatient visits to the adolescent clinic, 2000 visits to the emergency department, and 600 medical inpatients. During the study period (1984 to 1987), 15% to 20% of primary diagnoses in the clinic were related to STDs (most commonly vaginitis and cervicitis). Approximately 25% of primary diagnoses involved reproductive concerns (contraception and pregnancy). These diagnoses reflect the preponderance of female patients (75%) in the clinic. About 13% of visits by males were related to STDs. Approximately 10% of inpatient admissions during the study period were for pelvic inflammatory disease.

Faculty supervision of house staff is provided by two pediatricians and one internist specializing in adolescent medicine as well as a pediatric infectious diseases specialist. A faculty member is always available on site for individual consultation with residents during clinic hours.

Prior to implementation of the model STD curriculum, residents received approximately 4 hours of formal instruction on STDs annually. Senior internal medicine residents participating in an elective infectious diseases rotation had the opportunity to attend the Oklahoma City-County STD Clinic for 4 hours weekly during that period.

Needs Assessment

During the first year of the project (1984-1985), a needs assessment questionnaire was distributed to residents during their adolescent medicine rotation. Physicians were asked to provide demographic data anonymously (including level of training and previous STD and adolescent medicine experience) and to rate the importance of competence, current self-perceived competence, and interest in learning about 16 STDs and related topics. These topics are included in the learning objectives of the STD curriculum (see below). Ratings on a five-point Likert scale were obtained for importance, competence, and interest for each topic. A

rating of 1 was lowest ("not") and a rating of 5 was highest ("very") in each scale, eg, for the "importance" scale, 1 = not important, 5 = very important. (The questionnaire is available on request.)

STD Curriculum

Eighteen learning objectives were identified and stratified into two levels. Nine basic objectives were included in level 1 and presented to house staff during the second year of the project (1985-1986). Level 1 focused on physical and laboratory assessment of patients with suspected STDs, special concerns regarding adolescents with STDs, and common STD syndromes, such as vaginal discharge and mucopurulent cervicitis. During the third year (1986-1987), material was added to the level 1 content. The learning objectives for level 2 consisted of less-common STDs, such as epididymitis and cutaneous syndromes, and specialized topics, including STDs in children and in homosexual patients.

Formats utilized in presentation of the curriculum to house staff included lectures, discussions, videotapes, a plastic teaching model of the female pelvis, laboratory demonstrations, and a manual written by one of the project directors. Attending faculty on the inpatient service lectured and led discussions on attending rounds for approximately 6 hours each month. One of the curriculum project directors (P.J.R.), a pediatric venereologist, attended one half day weekly in the adolescent clinic. House staff were encouraged to present unusual or problematic cases to him.

Residents participated in an STD training session at the beginning of the rotation. This 1½-hour overview used a videotape ("Pelvic Examination of the Female with Sexually Transmitted Disease," provided by the Centers for Disease Control, Atlanta, Ga) and a plastic pelvic teaching model to introduce necessary clinical skills. Discussion emphasized the need to consider STDs in adolescents within the context of developmental issues and risk-taking behaviors. The session was completed by demonstration of potassium hydroxide, normal saline wet preparation, and Gram's stain smear techniques for evaluation of genital secretions. Teaching slides illustrating these techniques were reviewed using a multiheaded microscope.

A manual entitled *STDs: Specially Teen-aged Diseases* was written by one of us (P.J.R.) in a problem-oriented format encompassing level 1 learning objectives. This manual, which emphasizes the biologic, psychosocial, and legal aspects of STDs that are unique to adolescents, was distributed to each resident at the beginning of the rotation. (The manual is available for a nominal fee from one of us [J.J.].)

Implementation

Residents on the adolescent medicine rotation between July 1, 1985, and June 30, 1986, participated in the level 1 curriculum. Level 2 material was then introduced, so that all residents on the rotation between July 1, 1986, and June 30, 1987, were presented with both the level 1 and the level 2 curricula.

Knowledge Assessment

Pretests and posttests were administered to assess learning attributable to the curriculum. K-type multiple-choice questions were developed in part from materials used in Centers for Disease Control STD training courses and by the Oklahoma State Department of Health; additional original questions relevant to adolescent medicine concerns were formulated. The items were evaluated for validity and difficulty by administering them to selected third-year residents and infectious disease fellows. Of items chosen for use in program evaluation, 50 pertained to level 1 learning objectives and 38 were relevant to level 2. Ten items for the level 1 test and 4 for the level 2 test included a pictorial component. To assess changes in knowledge about the level 1 material, the 50 items were administered to house staff in each month of the level 1 curriculum in a pretest-posttest format. Questions on the pretest were randomly reordered to form the posttest. The examination was administered in a split-half design to evaluate the influence of pretesting on posttest scores. Half of the residents were randomly assigned to take the pretest at the beginning of the rotation; all took the posttest at the end of the rotation. Residents were asked to identify themselves by birth date and social security number only. During the second year of the project, when material related to both level 1 and level 2 was presented, all residents completed both the pretest and posttest, consisting of the 38 items related to level 2 learning objectives. Several items were revised after the first four testing cycles. (The tests are available on request.) Approval to administer the tests was obtained from the Institutional Review Board of the University of Oklahoma Health Sciences Center.

Data Analysis

Needs Assessment.—Statistical analysis was performed using the Statistical Analysis Systems package, version 5.16,⁹ and using the ABstat statistical package, release 4.¹⁰ A composite "interest" index (maximum, 100 points) was derived from interest ratings for the 16 STD-related topics. Independent *t* tests were used as appropriate.

Knowledge Assessment.—Raw scores of examinations taken by pediatric and medicine residents in each year of the project

Table 1.—Pretest and Posttest Scores						
	Possible Points	Pretest		Posttest		P
		Mean (SD) Score	No. of Subjects	Mean (SD) Score	No. of Subjects	
Level 1*						
Pretested subjects	50	24.0 (3.9)	51	26.9 (5.1)	50	.0001
Nonpretested subjects	50	28.1 (5.0)	50	...
Level 2						
Original version	38	22.7 (3.6)	33	24.3 (3.1)	32	.004
Revised version	38	17.7 (3.4)	61	19.7 (3.5)	59	.001

*Subjects who had taken the pretest did not score higher on the posttest than subjects who had not taken the pretest ($P = .23$).

Table 2.—Scores of Medicine and Pediatric House Staff (Level 1)						
	Possible Points	Medicine		Pediatrics		P
		Mean (SD) Score	No. of Subjects	Mean (SD) Score	No. of Subjects	
Pretest	50	23.6 (4.0)	27	24.5 (3.8)	24	.43
Posttest	50	28.7 (5.0)	45	26.5 (4.9)	56	.026

were analyzed separately using the Statistical Analysis Systems package, version 5.16. For level 1, scores for the six learning objectives, represented by at least five questions on the test, were further analyzed. All P values reported are for independent t tests, except for comparisons of individual residents with themselves, when paired t tests were used.

Approval to conduct the study was obtained from the Institutional Review Board of the University of Oklahoma Health Sciences Center.

RESULTS

Needs Assessment

Of 73 residents on the rotation during the needs assessment phase, 64 (88%) completed the questionnaire. Thirty-four were pediatric and 30 were medicine residents. There were 28 first-year, 19 second-year, and 17 third-year residents. Forty-five were men. About half (33 residents) had previously served on the adolescent medicine service. Residents thought it was quite important for physicians to increase their skill in treating patients with STDs during residency training (mean rating, 4.4) and were quite willing to provide health care for adolescents with suspected STDs (mean rating, 4.3). General self-perceived clinical competence in

managing STDs was somewhat lower (mean rating, 3.6), as was the level of interest in learning about STDs (mean rating, 3.9). The mean perceived competence rating was higher for level 1 (3.7) than for level 2 (2.7) topics. Analysis of ratings for individual learning objectives revealed that residents believed both level 1 and level 2 objectives were quite important (mean ratings, 4.6 and 4.2, respectively) and that they were interested in learning about both sets of objectives (mean rating, 3.8 for each set of objectives). Acute dysuria in females, epididymitis, and genital ulcers were of particular interest. The overall "interest" index of pediatric residents did not differ from that of medicine residents (77.9 vs 80.4, $P = .48$). Female medicine residents had a significantly higher mean interest index (92.8) than both male medicine residents (76.2, $P < .02$) and female pediatric residents (76.7, $P < .01$).

Knowledge Assessment

Level 1.—During the 1985-1986 academic year, 45 medicine and 56 pediatric residents participated in the level 1 curriculum; 41 were in their first postgraduate year. Pretest and posttest results are shown in Table 1. The mean score

increase calculated by paired t test was 4.4 points ($P = .0001$).

Scores of pediatric and medicine house staff are compared in Table 2. Although pretest scores did not differ, posttest scores of medicine residents were higher than those of pediatric residents. Scores of first-year residents did not differ from those of second- and third-year residents on either the pretest ($P > .06$) or posttest ($P > .08$).

Level 2.—Fifty medicine and 44 pediatric residents participated during the 1986-1987 academic year; 35 were first-year residents. Two residents did not complete the posttest. Test scores are found in Table 1. The mean score increase as calculated by paired t test was 1.8 points ($P < .0001$). Residents who had participated in the level 1 curriculum did not score differently on either the pretest or posttest than those who had not participated ($P > .15$). There was no relationship between mean score and medical specialty ($P > .40$) or level of training ($P > .19$).

COMMENT

It has been suggested that pediatric residency programs lack a core curriculum built around educational objectives¹¹ and that these programs may underemphasize education by stressing training.¹¹ The model STD curriculum described herein was developed and implemented according to specified learning objectives. It represents an effort to rectify previously described deficiencies in house staff education about STDs.⁷ Data collected during needs assessment indicated that house staff were interested in providing care for adolescents with STDs. There was a discrepancy between self-assessed competency in managing STDs and the perceived importance of these skills. Residents were more interested in learning about less commonly seen conditions. These findings are consistent with previously reported data.¹²

This curriculum differs from other educational programs developed for house staff in that knowledge change associated with implementation of the curriculum was evaluated. The examinations did not assess clinical skills, nor did they reassess attitudes toward treating patients with STDs. Comparison of mean pretest and posttest scores

revealed a modest but significant improvement in posttest scores that, in the level 1 testing, was shown not to be attributable to recall from the pretest. It is possible that the increase in posttest scores would have been greater had the pretest been less difficult. Also, the test may have underemphasized areas in which the most significant objective learning occurred. Although the curriculum was the primary intervention that might be expected to influence posttest scores, a learning effect due solely to clinical practice in evaluating patients with STDs might contribute to the increase in posttest scores. However, upper-level residents who had a rotation in adolescent medicine before the curriculum was presented did not score higher on pretests than did first-year residents. This suggests that these residents had either not acquired significant knowledge about STDs as measured by the test during their previous rotation or that a knowledge increase had occurred but was no longer mea-

surable at the beginning of the subsequent adolescent medicine rotation. It would be desirable to assess the persistence of the knowledge changes reported herein.

Level 1 posttest scores of medicine residents were slightly but significantly higher than those of pediatric residents, although pretest scores did not differ. This difference did not persist on the level 2 test. Medicine residents as a group had not been more interested in learning about STDs in the needs assessment. It is possible that personal attributes and experiences of medicine residents enabled them to learn more effectively from part of the curriculum. A previous study¹³ found that medicine residents in our training program were more likely than pediatric house staff to have experimented with drugs, to have begun sexual intercourse before age 21 years, and to have experienced an unplanned pregnancy.

It has been suggested that self-assessed competence in reproductive and

adolescent medical issues may be factors in the willingness of physicians to provide care for adolescents.¹⁴ A 1-month adolescent medicine rotation has been reported to improve pediatric residents' self-assessed competence.¹⁵ Experience in an adolescent clinic over an extended period for a total of approximately 30 hours, however, was not found to increase the interest or self-assessed skill of the pediatric house staff in adolescent medicine.¹⁶ Utilizing a thoughtfully planned and implemented curriculum within an adolescent medicine rotation should not only increase knowledge, as did our STD curriculum, but also may enhance physician willingness and confidence in serving as care providers for adolescents.

This project was funded as a Demonstration Project by the Centers for Disease Control, Atlanta, Ga (grant R30/CCR600688). It was facilitated by the participation of the Oklahoma State Department of Health (Gregory R. Istre, MD; H. Dan Cameron, MPH; and Beth Dahl, RN) and the support of Rebecca J. Beckman, MD.

Acute Changes in Renal Function Associated With Deferoxamine Therapy

Gideon Koren, MD; Yedidia Bentur, MD; Dawn Strong, PharmD; Elizabeth Harvey, MD; Julia Klein, MSc; Reuben Baumal, MD, PhD; Stephen P. Spielberg, MD, PhD; Melvin H. Freedman, MD

• In three patients who received intravenous deferoxamine there was a twofold to eightfold increase in plasma creatinine level and a parallel decrease in creatinine clearance that resolved when treatment with the drug was discontinued. In two thalassemic patients, diuresis was evident by urine output exceeding fluid intake. The mechanism was studied in dogs that exhibited an acute and significant decrease in inulin and para-aminohippuric acid clearances induced by intravenous deferoxamine. Saline diuresis could prevent the decrease in the glomerular filtration rate but not the decrease in renal blood flow caused by deferoxamine. Deferoxamine induced an acute increase in the fractional excretion of sodium, potassium, chloride, phosphate, and urate, which may explain the relative diuresis observed in two of the patients. In a subsequent experiment, ferrioxamine induced an increase in the fractional excretion of sodium and chloride but did not affect the glomerular filtration rate and renal blood flow. Our studies suggest that adequate hydration may be needed to preserve renal hemodynamics during intravenous deferoxamine therapy. Repeated measurements of renal function should accompany treatment with this agent. (AJDC. 1989;143:1077-1080)

Deferoxamine is widely used as a chelator in cases of acute or chronic iron overload.¹ In acute iron overload due to

accidental ingestion of iron pills, deferoxamine is generally administered for a few days, and patients with transfusion-dependent thalassemia are treated by nightly subcutaneous infusions of deferoxamine using a battery-powered syringe pump. For many years this mode of therapy has been assumed to be safe; however, recent studies from our service have documented serious neurotoxicity induced by long-term deferoxamine therapy, with transitory or permanent hearing and visual losses.^{2,3} We report acute changes in renal function observed in three patients receiving intravenous deferoxamine infusions. A subsequent animal study confirmed the causal relationship between deferoxamine and renal adverse effects.

PATIENT REPORTS

In April 1987, three cases of acute renal failure were documented during intravenous deferoxamine therapy at The Hospital for Sick Children, Toronto, Canada. Patients 1 and 2 suffered from thalassemia major and were treated for several years with nightly subcutaneous infusions of deferoxamine to remove transfusional iron overload. Because of their poor compliance with this regimen and increasing evidence of cumulative iron burden, they were hospitalized for intensive deferoxamine therapy, 10 mg/kg per hour, 18 hours per day, for 7 days. Patient 3, a 2-year-old girl, was treated with deferoxamine for short-term ingestion of ferrous fumarate tablets.

PATIENT 1.—A 21-year-old Portuguese man (67 kg) with thalassemia major had begun subcutaneous deferoxamine therapy in 1980. Despite this, congestive heart failure developed in 1983, and he was given digoxin hydrochlorothiazide and spironolactone. Prior to admission he had been receiving monthly blood transfusions and was given subcutaneous deferoxamine, 10 mg/kg per hour, five nights per week. Because his serum ferritin level 4 weeks prior to admission was 7976 μ g/L, he was admitted for daily intravenous deferoxamine infusions.

On admission, serum laboratory values were as follows: ferritin, 5300 μ g/L (normal range, 16 to 300 μ g/L); creatinine, 93 μ mol/L;

urea nitrogen, 8.2 mmol/L; hematocrit 0.412; and glucose, 6.4 mmol/L. He had an estimated serum osmolality of 277 mmol/kg. Intravenous deferoxamine therapy was begun at a dosage of 10 mg/kg per hour given in 250 mL of saline for 18 hours daily. The infusions were associated with abdominal pain radiating to his back and nausea and vomiting; however, his systemic blood pressure and heart rate were stable throughout deferoxamine therapy. Overall, his urine output was twice his fluid intake from day 3 to day 1 of deferoxamine therapy. Creatinine clearance decreased during his deferoxamine therapy (Fig 1), and on the 13th day of the protocol he had the following serum laboratory values: creatinine, 262 μ mol/L (Fig 2) urea nitrogen, 20.6 mmol/L; ferritin, 446 μ g/L; and glucose, 7.4 mmol/L; his weight was 62.3 kg. Deferoxamine therapy was discontinued, and on day 14 his serum glucose level was 17.9 mmol/L; serum osmolality, 281 mmol/kg; and urine osmolality, 417 mmol/kg. Over the following 5 days the serum creatinine and urea nitrogen levels began to decline, and on discharge the serum creatinine level was 77 μ mol/L and the urea nitrogen level was 10.4 mmol/L, similar to the value before high-dose deferoxamine therapy was started (Fig 2).

PATIENT 2.—An 18-year-old Chinese man (57 kg) with thalassemia major was admitted for daily intravenous infusion of deferoxamine due to increasing serum ferritin concentrations. Prior to admission he had been receiving nightly deferoxamine, 10 mg/kg per hour, subcutaneously and ascorbic acid, 100 mg/d. Despite therapy his serum ferritin level on admission was greater than 14 000 μ g/L, which was postulated to represent poor compliance with his home deferoxamine therapy. Admission serum laboratory values were as follows: creatinine, 68 μ mol/L; urea nitrogen, 6.4 μ mol/L; hematocrit, 0.378; and glucose, 5.8 mmol/L. Following a blood transfusion, treatment was started with intravenous deferoxamine, 10 mg/kg per hour over 18 hours each day, and ascorbic acid, 500 mg orally per day. He tolerated the infusion well; however, overall, from day 5 to 10 his urine output was greater than his fluid intake. On the 10th day of intravenous deferoxamine his serum creatinine level was 101 μ mol/L (Fig 2); serum urea nitrogen, 6.2 mmol/L; hematocrit, 0.463; and weight, 55.4

Fig 1.—Acute decrease in creatinine clearance in patients 1 (open squares) and 2 (solid diamonds) during intravenous deferoxamine therapy.

Fig 2.—Acute increases in serum creatinine level in patients during intravenous deferoxamine therapy, with subsequent improvement after discontinuation of the drug.

kg. Creatinine clearance continued decreasing throughout the infusion of deferoxamine (Fig 1). His blood pressure and heart rate remained unchanged. Deferoxamine therapy was discontinued on day 18, and he had the following serum laboratory values at discharge 2 days later: creatinine, 116 µmol/L; urea nitrogen, 7.9 mmol/L; and ferritin, 9146 µg/L. In a follow-up measurement 1 month later his serum creatinine level was 65 µmol/L.

PATIENT 3.—A 2-year-old white girl was admitted to the hospital for the treatment of accidental iron overdose 7 hours following ingestion of an unknown quantity of ferrous fumarate tablets belonging to her mother.

On physical examination the 10.7-kg girl had a heart rate of 120 beats per minute, a respiratory rate of 36/min, and a blood pressure of 86/60 mm Hg. She was lethargic, coughing, and vomiting and had black stools. She had the following serum laboratory values: ferritin, 284 µg/L; creatinine, 35 µmol/L; urea nitrogen, 10.2 mmol/L; glucose, 12.8 mmol/L; hematocrit, 0.409; and osmolality, 305 mmol/kg.

Fluids and deferoxamine (10 mg/kg per

hour) were administered intravenously. A day after deferoxamine chelation therapy was initiated, the child had very low urine output (30 mL for 24 hours) despite good hydration, blood pressure of 90/60 mm Hg, and heart rate of 100 beats per minute. Her serum creatinine level had increased to 191 µmol/L and serum urea nitrogen level to 17.5 mmol/L (Fig 2). Urinalysis revealed proteinuria (2⁺) and heme granular casts. Urine osmolality was 166 mmol/kg, and her sodium level was 60 mmol/L. Thirty hours after deferoxamine therapy began her serum iron level was 87 µmol/L, her hematocrit was 0.2820 without apparent bleeding, and her body weight was increased to 11.4 kg. Subsequently, deferoxamine therapy was discontinued; serum creatinine and urea nitrogen levels continued to rise for the next 24 hours and reached a maximum of 247 µmol/L (creatinine) and 18 mmol/L (urea nitrogen). An abdominal ultrasound at this time demonstrated a mild increase in kidney size with bilateral diffuse echogenicity, consistent with renal parenchymal injury.

Over the next 6 days her urine output increased, and her serum creatinine and urea

nitrogen levels declined (Fig 2). The serum creatinine level had returned to baseline at a clinic visit 2 weeks later.

ANIMAL STUDIES

Eight mongrel dogs that had free access to food and water prior to the experiments were premedicated with acepromazine maleate (1 mg/kg), anesthetized with pentobarbital (10 mg/kg), and mechanically ventilated. The external jugular veins, femoral artery, and both ureters were cannulated. An intravenous bolus of inulin (40 mg/kg) and para-aminohippuric acid (7 mg/kg) was followed by continuous infusion (inulin, 0.88 mg/kg per minute, and para-aminohippuric acid, 0.34 mg/kg per minute). After 40 minutes of equilibration at a saline infusion rate of 5 mL/kg per hour, 20-minute urine samples were collected with midinterval serum samples for calculation of inulin and para-aminohippuric acid clearances and for the determination of sodium, potassium, chloride, phosphate, and urate concentrations. Clearances were calculated as the ratio between the amount of a compound excreted in the urine in 1 minute and its midcollection plasma concentration. Fractional excretion was calculated as the ratio between the electrolyte clearance and that of inulin. After baseline measurements of clearance, deferoxamine (Desferal, Ciba-Geigy Corp, Summit, NJ) was infused at a rate of 10 mg/kg per hour for 2 hours. One hour after discontinuation of deferoxamine infusion, blood was drawn for deferoxamine determination, and the dogs were infused with saline at 40 mL/kg per hour to produce excessive diuresis (urine rate of 0.28 ± 0.086 mL/kg per minute); subsequently, deferoxamine infusion was restarted at the same dosage schedule for another 2 hours. Measurements of inulin and para-aminohippuric acid clearance and the various anions and cations were repeated at the various steps of the experiment (Fig 3). Arterial blood pressure was continuously measured by a manometer attached to an indwelling catheter at the left femoral artery. Infusion of all fluids was controlled by infusion pumps.

In another set of experiments, ferrioxamine solution was prepared by adding deferoxamine in the amount equivalent to infusion of 10 mg/kg per hour for 2 hours to 55 mg of iron dextran (Imferon, Fisons Corp, Bedford, Mass). The amount of iron was calculated to be twice the amount expected to be chelated by deferoxamine (100 mg of deferoxamine for 8.5 mg of iron¹). This solution was infused at a rate equivalent to 10 mg/kg per hour of deferoxamine to three additional dogs. The experimental protocol was identical to that described above, except for the volume expansion phase, which was not repeated.

Inulin clearance was measured by the

Fig 3.—Changes in inulin and para-aminohippuric acid clearances in dogs treated with deferoxamine, 10 mg/kg per hour, with or without saline diuresis. Asterisk indicates $P < .025$ for the baseline value compared with the value at the end of deferoxamine infusion; dagger, $P < .025$ for the value at the end of deferoxamine infusion compared with the value one half hour after the end of deferoxamine infusion; double dagger, $P < .050$ for the value one half hour after the end of deferoxamine infusion compared with the value 15 minutes after hydration was begun; and section mark, $P < .005$ for the value 15 minutes after hydration was begun compared with the value one half hour after deferoxamine infusion and hydration were stopped.

method described by Schreiner⁴ and para-aminohippuric acid clearance was measured by the method of Smith et al.⁵

Serum concentrations of deferoxamine were measured by a new high-pressure liquid chromatography method developed in our laboratory.⁶ Briefly, the procedure involves the use of ciprofloxacin as an internal standard followed by ultrafiltration to remove protein. The ultrafiltrate is then directly injected into the chromatography system. Separation is achieved using a reverse-phase C18 column and a ternary solvent system running at 2 mL/min. The lowest limit of sensitivity is 0.2 mg/L, and the coefficient of variation within day is 4.5%. Data in different treatment periods were compared by paired Student's *t* test or analysis of variance whenever applicable. At the conclusion of each experiment, kidneys were removed and inspected by gross examination, and tissue sections were processed. The sections were stained with hematoxylin-eosin, phloxin and saffron, periodic acid-Schiff, and Masson trichrome.

RESULTS

There was a significant decrease in inulin and para-aminohippuric acid

Fractional Excretion Values Induced by Deferoxamine					
	Fractional Excretion (Mean \pm SD)				
	Sodium	Potassium	Chloride	Phosphate	Urate
Normovolemia					
Before deferoxamine	0.44 \pm 0.14	18.5 \pm 3.4	0.32 \pm 0.13	10.6 \pm 0.8	14 \pm 0.86
End of deferoxamine infusion*	1.5 \pm 0.3	23.5 \pm 3.9	0.8 \pm 0.13	22.3 \pm 5.4	28.1 \pm 7.6
1 h after deferoxamine infusion†	0.85 \pm 0.19	17.9 \pm 0.8	0.46 \pm 0.18	9.8 \pm 2.5	22.2 \pm 3.16
Volume expansion					
Before deferoxamine	6.95 \pm 0.05	35.8 \pm 5.6	8.6 \pm 0.9	45.8 \pm 3.7	44.4 \pm 2
End of deferoxamine infusion*	17.6 \pm 0.2	42.2 \pm 6.9	19 \pm 1	66 \pm 5.4	60 \pm 22.7
1 h after deferoxamine infusion	15.1 \pm 4	32.6 \pm 0.6	16.4 \pm 4.1	51 \pm 3.1	41.8 \pm 10.5
Before ferrioxamine	0.34 \pm 0.15	16.93 \pm 4.41
End of ferrioxamine infusion	1.38 \pm 0.69	21.1 \pm 3.94
1 h after ferrioxamine infusion	1.8 \pm 0.80	22.53 \pm 3.04

*All values were significantly higher at the end of the deferoxamine infusion compared with before deferoxamine ($P < .05$ by analysis of variance).

†All values were significantly higher before deferoxamine after the initiation of saline infusion compared with values before saline infusion ($P < .05$ by analysis of variance).

clearances when deferoxamine was infused at the normovolemic phase ($P < .025$, Fig 3). No changes in arterial blood pressure were noted before and after deferoxamine infusion (115 \pm 13 and 118 \pm 13 mm Hg, respectively). Following discontinuation of deferoxamine infusion, both clearances returned to their baseline values, and serum deferoxamine concentrations were undetectable. The volume expansion resulted, as expected, in a significant increase in inulin and para-aminohippuric acid clearances as well as an increase in the urine flow rate (from 0.0125 \pm 0.0014 mL/kg per minute to 0.285 \pm 0.086 mL/kg per minute, $P < .001$). After volume expansion, deferoxamine did not cause a significant decrease in inulin clearance, whereas para-aminohippuric acid clearance decreased significantly ($P < .005$). Deferoxamine induced a rapid and significant increase in the fractional excretion of sodium, potassium, chloride, phosphate, and urate ($P < .05$) when tested both in the normovolemic phase and during volume expansion. These values returned to their baseline levels after discontinuation of deferoxamine infusion in the normovolemic phase and decreased, although not to baseline levels, in animals that had undergone volume expansion (Table). Deferoxamine serum concentrations were undetectable. Ferrioxamine did not cause any significant change in

para-aminohippuric acid clearance (6.04 \pm 1.73 mL/min per kilogram before ferrioxamine infusion and 6.16 \pm 0.64 mL/min per kilogram at the end of ferrioxamine infusion) or inulin clearance (2.40 \pm 0.43 mL/min per kilogram before ferrioxamine infusion and 2.47 \pm 0.34 mL/min per kilogram at the end of ferrioxamine infusion). Ferrioxamine induced an increase in the fractional excretions of sodium (fourfold) and chloride (fivefold) in all three animal studies (Table). These values did not return to baseline levels after ferrioxamine infusion was stopped; in fact, they continued to increase. No changes in arterial blood pressure were observed.

The capsular surface of the kidney appeared dark blue, consistent with congestion. By light microscopy, there was dilatation and congestion of peritubular capillaries, interstitial blood vessels, and glomerular capillaries; however, no other abnormalities of renal structure were seen, and the tubule appeared normal.

COMMENT

The interpretation of the three cases presented herein is complicated. There is no consistent history pattern (age difference, acute vs chronic intoxication; short-term vs long-term treatment; and their clinical course was different (abrupt vs gradual increase in serum creatinine concentration). In addition

it is impossible to rule out the effects of iron on renal function.

Although these cases do not form a homogeneous group, deferoxamine may have played a role in the development of acute renal failure. A controlled animal model seemed to be the proper way to study the potential nephrotoxicity of deferoxamine.

The animals were treated with a similar dosage schedule used clinically for treatment of iron overload in the three patients. Studies from our laboratory reveal that serum concentrations of deferoxamine in patients and dogs receiving the same dosage were comparable (between 3 and 12 g/L).^{7,8} We tested the potential renal effect of deferoxamine during normovolemia and after volume expansion in the dogs.

Our animal study demonstrated acute decreases in the glomerular filtration rate and renal blood flow induced by deferoxamine, without changes in systemic blood pressure. Because the hematocrit was not changed before and during deferoxamine infusion, changes in para-aminohippuric acid clearance reflect alterations in renal blood flow. These renal hemodynamic changes were reversed after deferoxamine infusion was discontinued. During volume expansion we were able to prevent the decrease in the glomerular filtration rate. We also demonstrated deferoxamine-induced increases in fractional excretion of sodium, potassium, chloride, phosphate, and urate in both the normovolemic and volume expansion phases; these were partially reversed by discontinuing deferoxamine infusion. The absence of morphologic changes under light microscopy supports the hypothesis of functional impairment.

Two mechanisms may explain deferoxamine nephrotoxicity:

1. There may be an acute decrease in renal perfusion in the presence of unchanged systemic blood pressure. That volume expansion prevented the decrease in the glomerular filtration rate may suggest a similarity to some of the renal effects of nonsteroidal anti-inflammatory drugs.^{9,10} Renal hemodynamics during borderline hydration or dehydration are significantly dependent on vasodilating prostaglandins. Furthermore, anesthesia can also increase the renal prostaglandin output with activation of the renin angiotension system.

The inhibition of prostaglandin synthesis, as in the case of nonsteroidal anti-inflammatory drugs, may be detrimental. It is still to be determined if deferoxamine affects prostaglandins; however, a recent report¹¹ supports this proposition.

2. Inhibition of tubular reabsorption of salts may take place, causing solute diuresis. Of interest are the findings that ferrioxamine induced an increase in the fractional excretion of sodium and chloride but did not cause any change in the glomerular filtration rate and renal blood flow. This ferrioxamine-induced tubular injury may suggest dissociation between the two observed effects of deferoxamine; that is, deferoxamine induced the renal hemodynamic changes whereas its iron chelate, ferrioxamine, caused the increased solute excretion. A synergistic effect between deferoxamine and ferrioxamine may exist as well, and further studies are needed.

Acute renal failure associated with deferoxamine therapy has been reported in a few cases^{12,13}; however, no attempt was made to prove causation, and a prerenal mechanism has been postulated. The high intravenous dose of deferoxamine used in patients 1 and 2 is much higher than the routine nightly subcutaneous infusion of the drug, suggesting a dose-related phenomenon. This suggestion is supported by Batey et al,¹¹ who found that increases in serum creatinine occurred only with the higher doses of deferoxamine (3 g/d for 2 days).

Our finding of increased solute excretion in the animal model may explain the relative diuresis seen in the two older patients with chronic iron overload and long-term deferoxamine treatment (possibly associated with higher ferrioxamine levels). This diuresis may have eventually caused volume contraction and prerenal azotemia. The toddler treated for acute iron intoxication presented with acute tubular necrosis, which may be explained by acute renal hemodynamic changes, as evidenced in the animal model. It is possible that both mechanisms had a role in the development of the acute renal failure in our patients; however, one cannot exclude one mechanism in the acute case and the other mechanism in the chronic case. In the past, renal damage seen during acute iron overdose was explained

mainly by the acute hemodynamic changes and possibly by a yet-unproved direct deposition of iron in the kidney. Our studies indicate that high-dose deferoxamine may be an important factor in affecting renal function during acute overdose.

To our knowledge, this is the first experimental proof of deferoxamine nephrotoxicity. Although more studies are needed to elucidate the mechanisms underlying this phenomenon, adequate hydration and repeated measurements of renal function should accompany intravenous deferoxamine therapy to prevent and detect possible renal failure.

This study was supported in part by grant MA 8544 from the Medical Research Council of Canada, Ottawa, and by a grant from Pediatric Consultants Inc, Toronto, Canada.

Methylphenidate in Children With Seizures and Attention-Deficit Disorder

Heidi Feldman, MD, PhD; Patricia Crumrine, MD; Benjamin L. Handen, PhD;
Rose Alvin, RN, PhD; Janet Teodori, MD

• This study assessed the safety and efficacy of methylphenidate in children with seizures and attention-deficit disorder. Ten children, aged 6 years 10 months to 10 years 10 months, without seizures while receiving a single antiepileptic drug, were evaluated in a double-blind medication-placebo crossover study with methylphenidate hydrochloride was administered at 0.3 mg/kg per dose and given at 8 AM and 12 PM on school days only. The use of methylphenidate was associated with statistically significant improvements on the Conners' Teacher Rating Scale and on the Finger Tapping Task and with trends toward improvement on the Matching Familiar Figures Test and Discriminant Reaction Time tests. No child had seizures during the study period nor subsequently for those who continued receiving psychostimulants. There were no significant changes of epileptiform features or background activity on electroencephalograms and no alterations in antiepileptic drug levels. Methylphenidate may be a safe and effective treatment for certain children with seizures and concurrent attention-deficit disorder.

(AJDC. 1989;143:1081-1086)

One of the major treatment options for children with attention-deficit disorder (ADD) is pharmacologic intervention with methylphenidate hydrochloride, a psychostimulant effective in prolonging attention, decreasing impulsivity, quieting hyperactivity, and improving classroom behavior.¹⁻⁶ The use of methylphenidate in children with seizures, whether or not they receive anticonvulsant therapy, is actively dis-

couraged by CIBA Pharmaceutical Company, the manufacturer of methylphenidate (Ritalin). The package insert and the *Physicians' Desk Reference*⁶ state that

there is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG [electroencephalographic] abnormalities in the absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Many physicians, heeding these warnings, eliminate the option of methylphenidate therapy for children with the dual diagnoses of seizures and ADD.

Objective evidence for methylphenidate as an analeptic is scanty. The manufacturer cites rare clinical case reports. Previously, however, before monitoring the serum levels of antiepileptic drugs (AEDs) was available routinely, psychostimulants, including methylphenidate, had been used routinely in patients with seizures to counteract the sedative side effects of the AEDs.^{7,8} Dextroamphetamine sulfate, a related psychostimulant, was used as an adjunct AED for absence seizures.^{9,10} A recent retrospective study reviewed a cohort of 23 children who had either seizures or epileptiform features on electroencephalograms (EEGs) plus ADD.¹¹ The addition of methylphenidate to an AED regimen neither increased the frequency of seizures nor produced seizures in those with abnormal EEGs.

The goal of our study was to evaluate systematically the safety and efficacy of methylphenidate therapy for children with seizures and concurrent ADD, using a carefully controlled, "blinded" study design. We hypothesized, based on clinical experience and pilot data,

that methylphenidate would be effective in this population, as measured by standard behavioral questionnaires, laboratory studies sensitive to drug effects, or both. More importantly, using three criteria for safety, we hypothesized that methylphenidate would be safe. The first criterion was that there would be no increase in seizure frequency. The second criterion was that EEGs would not show increases in epileptiform activity. Previous studies of nonepileptic children have used the EEG as a predictor or parameter of improvement during methylphenidate therapy¹²⁻¹⁴ but have focused on background disturbance, not epileptiform features. The final criterion was that AED levels would not change with the introduction of methylphenidate. Previous studies of patients receiving multiple AEDs and of adult volunteers have reported varying effects of methylphenidate on AED levels.^{7,8,15}

SUBJECTS AND METHODS

Subjects

Ten patients from the Division of Child Neurology or Child Development Unit, Children's Hospital of Pittsburgh (Pa) (eight boys and two girls) aged 6 years 10 months to 10 years 10 months served as subjects. Table 1, organized by AED, provides age, sex, seizure type, educational level, and classroom placement for each subject.

The diagnosis of epilepsy, classification of seizure type, and choice of AED were established by child neurologists. The conditions of all the children were well controlled, with no seizures for at least 3 months preceding the study, as documented by medical histories. All of the children were receiving a single AED, with levels documented in the therapeutic range at the outset of the study. Five subjects had partial complex seizures, two generalized tonic-clonic seizures, two generalized atonic seizures, and one partial elementary motor seizure with secondary generalization. The AEDs included carbamazepine,

Table 1.—Patient Characteristics

Patient No.	Sex/Age, y	Antiepileptic Drug	Seizure Type	Previous Stimulant Use	Grade	Class*
1	M/6.10	Carbamazepine	Partial complex	No	1-2	BD
2	M/10.6	Carbamazepine	Partial complex	Pemoline	5	LD
3	M/8.3	Carbamazepine	Partial complex	No	2	Mainstream
4	M/10.9	Carbamazepine	Partial complex	Methylphenidate hydrochloride	5	Mainstream
5	M/10.10	Carbamazepine	Generalized tonicoclonic	Methylphenidate	4	SED
6	M/6.11	Phenytoin sodium	Generalized atonic	No	2	Mixed MR/SED
7	F/7.5	Phenobarbital sodium	Generalized tonicoclonic	No	2	LD
8	M/8.0	Phenobarbital	Partial motor with secondary generalization	No	2	Mainstream
9	M/9.4	Valproic acid	Partial complex	Methylphenidate	4	LD/MR
10	F/8.1	Valproic acid	Generalized atonic	No	2	Mainstream

*BD indicates brain damaged; MR/SED, mixed category for mentally retarded and socially and emotionally disturbed; and LD, learning disabled.

phenobarbital, phenytoin, and valproic acid, with the largest subpopulation receiving carbamazepine ($n=5$). The parents of the two children receiving phenobarbital reported that attention problems or hyperactivity began before the use of phenobarbital and that the symptoms did not change with use of a different AED or reintroduction of phenobarbital therapy.

Children were identified for enrollment because of parental or school concerns of inattention or overactivity. The diagnosis of ADD with or without hyperactivity was established in a clinical interview with a parent(s) by a developmental pediatrician using criteria from the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition*¹⁶ and confirmed with the Revised Conners' Parent and Teacher Behavior Rating scales.¹⁷ On these scales, behavior characteristics are rated on a four-point scale from "not at all" to "very much." Ten items on each scale form the Hyperactivity Index. Raw scores on the Hyperactivity Index were converted to age- and sex-normed z scores.¹⁷ Each child scored 1.5 SDs or more above the mean for age and sex on this scale. Three children were receiving psychostimulants at the time of recruitment but had not had systematic monitoring of seizure frequency, AED levels, or EEGs while receiving methylphenidate. These children were given a 2-week drug-free period before beginning the study, after which the baseline questionnaires were obtained. One subject had been receiving methylphenidate a year before the study. Children were not excluded on the basis of IQ. The protocol was approved by the Children's Hospital of Pittsburgh Institutional Review Board. Written informed consent from parents and verbal assent from children were obtained at the first visit.

Study Design

The study used a double-blind methylphenidate-placebo crossover design, with each subject serving as his or her own control. Methylphenidate hydrochloride was administered at 0.3 mg/kg per dose, rounded up to the nearest 2.5 mg, and was given twice a day, at 8 AM and 12 PM, on school days only. The lower end of the dosing range was selected to minimize the risk of seizures. The trials of methylphenidate-placebo lasted 4 weeks. There was a 2-week washout between trial periods because of the possible long-lasting effects of methylphenidate on the EEGs.¹⁸

Parents were instructed to call the study team if seizures occurred. Children were evaluated at baseline and at the midpoint and end of the 4-week trials. Each session was at the same time of day to avoid circadian fluctuations in AEDs. Psychological testing began 30 to 45 minutes after methylphenidate administration, and EEGs and serum AED levels were obtained about 2 hours after methylphenidate was administered—at its presumed peak level. At each visit, the parents were interviewed about clinical improvements, seizure activity, the toxic side effects of AEDs, and the side effects of methylphenidate. One child did not complete the placebo trial because his parents and teachers became very concerned about his increased activity and disruptiveness. We used baseline data for his placebo phase in the analyses of rating scales and laboratory testing.

Rating Scales

Teachers were asked to complete the 28-item Revised Conners' Teacher Rating Scale¹⁷ midway and at the end of each trial.

The individual items were grouped into four established factors, conduct problems, hyperactivity, inattention-passivity, and the hyperactivity index, as described by Goyette et al.¹⁷ The factor scores were used for data analysis. For most children, two questionnaires were given in each study trial, and the scores were averaged.

Parents were asked to complete the 48-item Revised Conners' Parent Rating Scale.¹⁷ The scores were handled analogously to the Teacher's Rating Scale. No changes were noted on the Parent Rating Scale, and the scores are not reported in this article.

Laboratory Tests

Children were tested at baseline to introduce them to the procedures and at the end of each trial. One child could not complete the battery because of intellectual limitations, learning problems, or both; the data for the laboratory tests comes from nine subjects.

A Discriminant Reaction Time Test, a computerized test of selective attention, was administered using a revision of the Lewis and Rennie¹⁹ Repeatable Cognitive-Perceptual-Motor Battery. The test involved the rapid presentation of numbers on a screen and required the child to depress a computer key at the appearance of a preselected target stimulus. Children could make errors of omission and commission. The rate of stimulus presentation increased by 5% after a correct response and decreased by 5% after an incorrect response or omission. The score reported was the final number of stimuli presented per minute; the higher the score, the greater the speed, accuracy, or both.

The Matching Familiar Figures Test,²⁰ a measure of reflectivity or impulsivity, required the child to identify which of six figures matched a simultaneously presented target stimulus. The procedure was modified such that the child made only a single response without feedback rather than responding until successful. This modification eliminated the possibility that the child would remember the correct response on later test administrations. The score on this test was the latency of response in seconds.

A Finger Tapping Task, a measurement of neuromotor output, was administered to assess the influence of attentional skills on neuromotor efficiency. The child tapped a Reitan finger counter mounted on a board, with separate trials for the dominant and nondominant hand. The score for each hand was the mean number of finger taps over five 10-second trials.

The Digit Span from the Wechsler Intelligence Scale for Children-revised, a measure of attention and immediate memory, required the child to repeat a random string of digits of increasing length. The method of administration followed the test protocol.²¹

Raw scores were converted to age-normed standard scores, with a mean of 10 and an SD of 3.

A spelling learning test and mathematics performance test were piloted. However, because of difficulty in establishing appropriate baseline levels of success across subjects, no consistent trends were noted, and the results are not reported.

EEG Findings

The EEGs were obtained before each trial (baseline 1 and 2) and at the end of each study trial for a total of four studies per child (except for the child who dropped out in the placebo trial). A 30- to 45-minute standard 16-channel EEG using the international 10-20 electrode placement was obtained approximately 2 hours after methylphenidate administration. Attempts were made to record brain waves during awake and sleep states.

The EEGs were read by a child neurologist experienced in pediatric EEG. The EEGs were assigned random numbers and interpreted blindly relative to the subject and study trial. Background abnormalities were defined as increased slower frequencies posteriorly relative to chronological age without sustained rhythmicity. Epileptiform features were defined as focal or generalized sharp waves, spikes, or spike and wave complexes. The EEGs were classified as normal, abnormal with background disturbance, abnormal with epileptiform features, or abnormal with both background disturbance and epileptiform features. A second review was completed with the EEGs organized sequentially by subject with the reviewer blinded to the study phase. On this review, the EEGs were analyzed for the severity of the abnormalities.

AED Levels

Serum AED levels were obtained at baseline and twice during each trial at the end of the week. All AED levels were obtained approximately 2 hours after methylphenidate administration. Specimens were analyzed in the same laboratory using a fluorescent polarization immunoassay. Values at baseline and within the methylphenidate and placebo trials were averaged separately for data analysis.

Final Interview

Five children continued receiving psychostimulants (four received methylphenidate and one received pemoline) for 3 to 12 months after the study period based on clinical efficacy and parental preference. During the preparation of this report, the parents of these children were recontacted by telephone. They were questioned about further seizures and drug side effects.

Table 2.—Mean Scores on Factors of Conners' Teacher Rating Scales During Placebo and Methylphenidate Trials

Factors	Placebo	Methylphenidate Hydrochloride	No. of Children Improving While Receiving Methylphenidate
Conduct	7.85 ± 7.53	5.60 ± 5.35	6
Hyperactivity	10.75 ± 5.51	6.65 ± 3.97*	7
Inattention	10.60 ± 4.70	7.40 ± 3.66*	6
Hyperactivity index	15.25 ± 7.73	9.20 ± 5.91*	7

* $P < .05$.

Table 3.—Mean Scores on Laboratory Tests During Placebo and Methylphenidate Trials

Test	Placebo	Methylphenidate Hydrochloride	No. of Children Improving While Receiving Methylphenidate
Discriminant Reaction Time	23.91 ± 9.69	26.41 ± 11.05	5
Matching Familiar Figures			
Test Latency, s	8.20 ± 9.60	10.96 ± 8.51	8
Finger tapping			
No. of taps, dominant hand	32.23 ± 7.00	35.24 ± 7.96*	7
No. of taps, nondominant hand	28.33 ± 11.51	29.62 ± 10.73*	6
Digit Span			
standard score	8.3 ± 3.43	8.0 ± 3.40	4

* $P < .05$.

Data Analysis

A one-way repeated-measures analysis of variance was used to analyze subscales of the Conners' Teacher Rating scales, scores on the psychological tests, and AED levels for order effects. Order effects were not statistically significant, and the conditions were analyzed independent of order. A one-tailed paired t test compared the same scores in the placebo and methylphenidate phases.

RESULTS

Table 2 shows the average scores for the four factors of the Conners' Teacher Rating Scale. All four factors showed reductions during the methylphenidate trial, and the decreases on three of the factors reached statistical significance (hyperactivity: $t = 2.672$, $df = 9$, $P < .05$; inattention: $t = 2.154$, $df = 9$, $P < .05$; and Hyperactivity Index: $t = 2.457$, $df = 9$, $P < .05$).

The magnitude of the improvement during the methylphenidate trial was quantified by converting raw scores to age- and sex-normed z scores. On the Hyperactivity Index of the Conners' Teacher Behavior Rating Scale,¹⁷ the group averaged a 1.0-SD improvement, with a range from -1.31 to $+3.08$ SDs.

In the seven responders, the average improvement was 1.6 SDs.

Table 3 shows the results of the laboratory testing. There were significant improvements in the Finger Tapping Task with both the dominant hand ($t = 6.167$, $df = 8$, $P < .05$) and the nondominant hand ($t = 6.526$, $df = 8$, $P < .05$). On the Matching Familiar Figures Test, eight of nine children showed longer latencies while receiving methylphenidate, but the latency score did not achieve statistical significance ($t = 1.238$, $df = 8$). Performance on the Discriminant Reaction Time Test also showed a trend toward improvement using methylphenidate, with five children increasing their score ($t = 1.341$, $df = 8$, not significant). There was no systematic change in findings from the Digit Span.

None of the children had seizures during the study period according to the parents and teachers. Of the five children who continued receiving psychostimulants beyond the study period, none had seizures during the extended period. There were no dose-related toxic side effects of AEDs, such as visual disturbances, coordination problems, or

behavioral changes. Two parents reported mild side effects attributable to methylphenidate administration—appetite suppression and minor emotional lability. In both cases the effects were transient and did not alter drug treatment.

All but one patient had abnormal features on baseline EEG (Table 4). There were no significant changes from the first to second baseline or from baselines to study trials. The child with the normal EEG at baseline had normal EEGs throughout the clinical trials. No child with background abnormalities developed epileptiform features. One patient with epileptiform features at baseline had a normal EEG during the methylphenidate trial (Table 4).

Two patients with preexisting epileptiform features had minor changes during methylphenidate administration. One of these patients had prominent photoparoxysmal responses at baseline and during methylphenidate therapy but not during the placebo trial. Another patient had frequent bursts of generalized spike-wave complexes during the records of all trials but more frequent

bursts of 1- to 3-second duration during the methylphenidate trial (61.7 bursts per 60 minutes while receiving methylphenidate vs 29 at baseline and 40 while receiving placebo). No corresponding increases in the number of longer bursts lasting 3 to 5 seconds or greater than 5 seconds were noted. Although a video EEG was not obtained, there were no alterations in behavior or consciousness suggestive of seizures as observed by trained EEG technologists.

The AED levels fell in the subtherapeutic range on 5 of 58 determinations during the study. Twice there was poor compliance and once repeated vomiting on the day before determination. These 3 values were eliminated in further analyses because they were not relevant to the issue of drug interactions. On 2 determinations, once when methylphenidate was used and once when the placebo was given, a child whose dose of phenobarbital was maintained at the low end of the therapeutic range had levels in the subtherapeutic range. Average AED levels for each subject at baseline, methylphenidate, and placebo trials are presented in Table 5. The val-

ues are consistent across conditions. The mean level of carbamazepine for the five children receiving this AED was 8.09 during methylphenidate therapy and 8.41 during placebo therapy; these values were not significantly different ($t = 0.568$, $df = 4$).

COMMENT

The prevalence of the concurrent diagnoses of seizures and ADD is difficult to ascertain due to significant differences in definitions across studies. Ounsted,²² in an early study of epileptic children, reported that "hyperkinetic syndrome" was present in about 8% of cases, comparable with the 3% to 10% prevalence rate usually reported for ADD in nonepileptic American school children.²³ However, the descriptions of the disorder in that article²² and the associated mental retardation in 50% of the patients suggested that the term connoted extreme behavioral deviance. Prevalence rates might have been higher with the inclusion of milder variants of the syndrome. Rutter et al,²⁴ in their epidemiologic study from the Isle of Wight, reported that only 1 in 63 children with uncomplicated epilepsy had hyperkinetic syndrome, a lower rate than the usual American prevalence figures but comparable with estimates of ADD in school-aged nonepileptic British children.²⁵ These authors, however, found that 28% to 50% of children had symptoms of restlessness, fidgetiness, and poor concentration on parent and teacher questionnaires. Prevalence rates might have been higher using criteria from the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition* for ADD.

In the clinical practice of developmental pediatrics and child neurology, the problem of concurrent seizures and ADD is encountered regularly. The strong warning about methylphenidate treatment in children with seizures with abnormal EEGs who are receiving AEDs⁶ thrusts the clinician into a dilemma regarding treatment options. Many physicians do not consider prescribing methylphenidate to children with seizures because of medicolegal concerns. Frequently, there are additional intellectual and learning problems in these children,^{22,24} further complicating clinical decision making because of the lack

of articles on the use of methylphenidate in nonhospitalized mentally retarded children. In this sample, 60% of the children were in special educational programs.

The data from this study suggest that methylphenidate therapy may be an option for certain children with seizures and concurrent ADD. We were able to demonstrate that methylphenidate was efficacious in children with seizures. As in many other studies, questionnaire data provided by teachers was the most consistent indicator of the effect of methylphenidate therapy. Seven of 10 children improved on the Teacher's Behavior Rating Scale, a response rate comparable with that in many other studies.⁵ In this study, the failure of the Parent Rating Scale to show improvements during methylphenidate therapy was not surprising, since the half-life is 4 to 6 hours and we used a schedule of administering doses on school days only so that parents had minimal experience with their children at peak methylphenidate effects. Laboratory tests also confirmed the efficacy of methylphenidate therapy. The children were more efficient on the Finger Tapping Test while receiving methylphenidate. They seemed to use a more reflective, less impulsive approach on the Matching Familiar Figures Test and to improve selective attention on the Discriminant Reaction Time Test. In this intellectually heterogeneous sample, however, these two latter tests failed to achieve statistical significance because of extreme variability on performance.

The data suggest that methylphenidate may be used safely in children who have seizures that are well controlled on an AED regimen. No child had a clinical seizure during the study period or during subsequent use. The AED levels remained stable. Even in those five patients whose AED levels dropped to the

subtherapeutic range, there were no reported seizures. Patterns of epileptiform activity and background disturbance on an EEG did not systematically deteriorate during methylphenidate therapy. If seizure recurrence with methylphenidate is a rare complication, then a large sample would be required to demonstrate the risk. However, in this situation, the warning in the *Physicians' Desk Reference* could be modified.

The warning about methylphenidate use in children with abnormal EEGs is particularly confusing given the significant number of children with ADD and abnormal EEGs.²⁶⁻²⁸ In our cohort, 90% of subjects had abnormal EEGs, with 70% showing epileptiform features either alone or in combination with background slowing. Klinkerfuss et al²⁷ reported that 53% of their subjects with hyperkinesia and other neurologic problems, including seizures, had abnormalities on their EEGs.

No major changes in epileptiform features on the EEGs were associated with methylphenidate administration. The significance of epileptiform features on an interictal EEG is unclear. Epileptiform features are more likely to be present in subjects with a history of epilepsy than in the general population,²⁹ but whether increases in the number of epileptiform features correlate with changes in seizure frequency is not well documented. There are clearly many other variables associated with variations in epileptiform features, such as a change in state from wake to sleep and the use of drugs. In our sample, one child had changes in the frequency of one type of epileptiform activity but had no changes in clinical seizure pattern. A review of this child's EEGs before the study demonstrated that EEG patterns at earlier times were similar to the EEGs during methylphenidate therapy.

Therefore, we cannot relate the change only to methylphenidate administration. Sampling artifact remains a possibility for all the observed changes.

Despite these findings, continued caution in prescribing methylphenidate for children with seizures and ADD is warranted. First, all of the children in this study had well-controlled seizures with a seizure-free interval before enrollment. McBride et al,¹¹ however, noted that none of their patients who were having seizures at the time methylphenidate therapy was introduced had increases in seizure frequency. Second, the time course of the study was relatively short. However, the children who continued to use psychostimulants beyond the study period remained seizure free. Finally, our dosages of methylphenidate were at the low end of the effective range.

Our clinical experience has been that many physicians violate the warning and recommendations in the *Physicians' Desk Reference*.⁶ As with the use of methylphenidate for children with uncomplicated ADD, the use of methylphenidate in children with seizures and ADD should follow a careful diagnosis of ADD, clear demonstrations of clinical efficacy, and close monitoring of behavioral and neurologic complications. The use of methylphenidate should be integrated with other educational and behavioral treatments.

This research was funded by the Western Pennsylvania Chapter of the American Epilepsy Foundation, Pittsburgh, Pa.

The authors acknowledge William Pelham, PhD, for consultation on the study methodology, James Culbert, PhD, for the computerized Discrimination Reaction Time Test and consultation on the methodology, Beth Minnagh, PhD, and John Alvin, PhD, for consultation on the pharmacologic determinations, Michael Painter, MD, and the staff of the Child Development Unit for helpful suggestions on previous versions of the article, Carol Hallberg for manuscript preparation, and the children and their families for their participation in the study.

Attitudes Toward Mental Illness Prevention in Routine Pediatric Practice

Joel Yager, MD; Lawrence S. Linn, PhD; Barbara Leake, PhD;
Stephen Goldston, EdD; Christoph Heinicke, PhD; Robert Pynoos, MD

• Attitudes toward preventive mental health activities with high-risk children in clinical practice were surveyed in 316 pediatricians. Although generally positive attitudes were expressed regarding appropriateness and efficacy of such activities, uncertainty was expressed regarding the ethical issues and knowledge on which such activities rest. Pediatricians perceived serious barriers to preventive activities related to financial, educational, and time factors. Pediatricians whose personal health beliefs favored an internal locus of control were more positively inclined toward preventive activities. Studies relating reported attitudes and beliefs to actual practice patterns are necessary. Pediatricians also require additional training in mental health-related preventive activities.

(AJDC. 1989;143:1087-1090)

The prevention of illness and injury has traditionally played a major role in primary care pediatric practice. Although many of these practices relate to physical well-being,^{1,2} psychological and social aspects such as child abuse and learning disabilities also receive attention.³

The pediatrician is often the first health professional to identify opportunities for mental illness prevention. Yet, many opportunities for prevention are undoubtedly overlooked. For example, children of parents who are divorced, depressed, or hospitalized with major mental illnesses constitute major patient groups for prevention.⁴

Prevention efforts with these and other potential "high-risk" groups represent a departure from traditional pediatric practice. To our knowledge there are no previous studies regarding pediatricians' attitudes about what should constitute their proper roles in such situations. Therefore, we surveyed the attitudes of pediatric house staff, fellows, and academic and clinical (volunteer) faculty toward the appropriateness and efficacy of such mental illness prevention with high-risk children in their clinical work. In addition to developing reliable and valid scales to measure these attitudes, we hoped to identify perceived barriers to the initiation of preventive programs or activities in clinical situations.

We were also interested in identifying factors that may be significantly correlated with attitudes toward prevention such as pediatricians' age, sex, level of training or type of practice, earlier pre-medical school work experiences, career plans, and selected general beliefs about how people stay healthy. Studying the relationship between these factors and attitudes toward prevention may help researchers and educators develop a better understanding of how pediatricians develop different orientations toward prevention in clinical practice.

METHODS Design and Samples

The present study surveyed all PLI-III pediatric residents and those full-time academic faculty and clinical faculty actively involved with house staff supervision in the UCLA Department of Pediatrics affiliated with the UCLA Center for Health Sciences during the spring of 1987. Questionnaire items were modified from scales previously developed in a parallel study of psychiatrists'

attitudes toward prevention that had been validated using samples of physicians on the editorial boards of the *Journal of Preventive Psychiatry* and the *Journal of Primary Prevention* (N = 29).⁵

After two mailings, 316 of the questionnaires initially mailed were returned, constituting a 70% response rate. The percentages of the total sample of respondents consisted of the following groups: 16% house staff, 67% community-based clinical (volunteer) faculty, and 17% full-time academic faculty. The median age of the sample was 45 years; 26% were women; 90% were currently married; 92% were white; and 20% were Catholic, 20% were Protestant, 49% were Jewish, 11% had no expressed religion, and 1% had a religious affiliation that did not fall within our classification.

Measurements

Items measuring attitudes toward mental illness prevention were generated from the content of a training grant proposal in clinical preventive intervention written by several department faculty members and from an article on prevention written by Phillips.⁴ Specific modifications of items for pediatricians were written in consultation with members of Valencia Pediatric Associates, Newhall, Calif, a private practice group whose members are all active on the UCLA volunteer faculty. Equal numbers of positively and negatively worded items were written to avoid response bias, and respondents were asked to rate each item on a five-point scale from strongly agree to strongly disagree. Items were written to reflect three dimensions of attitudes toward mental health-oriented prevention in routine pediatric practice: role appropriateness for interventions with high-risk children, perceived efficacy, and perceived ethics of such interventions. Other items measured attitudes toward barriers potentially related to initiating preventive mental health measures such as insufficient time, financial constraints, inadequate knowledge or training, and patient resistance. These were not the only barriers that

could restrict preventive mental health activity in clinical practice but represented those thought to be most likely by our faculty group.

Physicians' health beliefs were measured by three health locus of control scales developed by Lau and Ware⁶: (1) the degree to which luck or chance influenced peoples' health status, (2) the degree to which people generally felt threatened by serious diseases, and (3) the degree to which people felt they could control their own health through self-care or preventive health behaviors. These scales were scored in such a way that higher scores indicated greater internal or self-control over health (and thus were less influenced by external forces such as serious disease or chance).

In addition to demographic characteristics such as age, sex, marital status, race, and religious affiliation, the pediatricians answered questions about the number of social sciences and humanities courses they took in college, whether they held an advanced degree other than the MD, how many vacation days they had taken in the past 12 months, how many hours a week they worked, how many research or clinical journals they read on a regular basis, and how many scholarly articles they had published in their careers. Respondents were also asked to estimate the likelihood of their pursuing eight career options on a scale of 0% to 100%.

Hypotheses

The following null hypotheses were tested: that there is no significant relationship between pediatricians' attitudes toward mental illness prevention and their demographic and social characteristics, health beliefs, educational background, or previous scholarly activity.

RESULTS

Scale Construction

Principal components factor analysis was used to test our conceptual model of attitudes regarding preventive mental health treatment. After inspection of factors with eigenvalues greater than 1.0, we decided to limit further analysis to eight factors. Varimax rotation was used to obtain meaningful factor constructs. Items were only included in scales if they had a loading greater than 0.49 on a factor with an eigenvalue greater than 2.0. Based on this analysis, Table 1 shows that we were able to construct five modestly reliable scales reflecting the dimensions of attitudes toward prevention and barriers that might inhibit such clinical activity.

Table 1.—Characteristics of Scales Developed to Measure Attitudes Toward Preventive Mental Health Activities in Routine Pediatric Clinical Practice

Scale	No. of Items	Average Item Score	SD	Range of Scores	Cronbach's α
Appropriateness*	6	4.15	0.45	2.67-5.0	.54
Efficacy*	11	3.55	0.52	1.82-4.73	.82
Ethics*	4	3.73	0.68	1.75-5.0	.60
Financial barriers†	2	2.05	0.82	1.0-5.0	.50
Education and time barriers†	3	2.61	0.82	1.0-5.0	.58

*Higher scores indicate more positive attitudes.

†Higher scores indicate that barriers are seen as more inhibiting.

Scale means were calculated based on the sum of the item scores (1 through 5) divided by the number of items in the scale. Higher scores on the appropriateness, effectiveness, and ethics scales indicated more positive attitudes. Higher scores on the two barrier scales (financial barriers and time and educational barriers) indicated greater belief in the barrier.

Illustrative items and responses from each of the five scales are presented in Table 2. Copies of the complete questionnaire, the 29 items making up the scales, and item-by-item responses are available on request from the senior author (J.Y.). Pediatricians almost always either strongly or somewhat agreed that preventive mental health-oriented interventions with high-risk children were appropriate. There was some uncertainty and almost no disagreement on most items. Generally two thirds or more of the sample felt that preventive measures were appropriate in the situations described (scale mean, 4.15).

Although generally favorable attitudes were expressed about the efficacy of prevention (scale mean, 3.55), there was considerable uncertainty and disagreement about whether the efficacy of prevention had been substantiated by research evidence.

As shown in Table 1, there was also favorable consensus in our sample that such preventive mental health measures were ethical (scale mean, 3.73). However, Table 1 also shows that there was strong consensus about two important barriers to preventive activities: financial issues (scale mean, 2.05) and time and educational barriers (scale mean, 2.61). Responses to items in

these scales indicated strong belief that neither patients nor third-party payers were willing or likely to pay for preventive mental health services. Similarly, there was general consensus that pediatricians lacked appropriate training to do prevention, and very divided opinion about whether pediatricians had sufficient time to be concerned about the mental health of their patients.

Some additional items measuring attitudes toward barriers did not form reliable scales. Responses to these items indicated that there was very divided opinion and much uncertainty regarding the pediatrician's role with the children of psychiatrically hospitalized parents. Similarly, pediatricians were divided in the degree to which they felt that preventive mental health practice entailed more uncertainty than other kinds of pediatric practice or whether mental health-oriented prevention was unlikely to become part of routine practice due to the usual orientation of physicians in which acute problems are the primary focus of concern. Finally, there was also disagreement regarding whether the organization of both residency training and private practice inhibited the initiation of preventive mental health-oriented practice.

In summary, our samples generally agreed that mental health-oriented prevention with high-risk children in routine clinical practice was very appropriate, ethical, and somewhat effective. They also generally believed that the lack of reimbursement for preventive services and the lack of adequate psychiatric training in prevention were significant barriers inhibiting the expansion of mental illness prevention.

Table 2.—Frequency Distributions of Illustrative Items From Five Scales Used to Measure Attitudes Toward Preventive Mental Health Activities in Routine Pediatric Clinical Practice

Items	% of Agreement				
	(5) Strongly Agree	(4) Somewhat Agree	(3) Uncertain	(2) Somewhat Disagree	(1) Strongly Disagree
Appropriateness					
It is the pediatrician's responsibility in treating a patient with serious illness to assess the extent to which the patient's family members have been affected psychologically.	64	34	1	2	0
Intervening in the lives of the children of a psychiatric patient constitutes high-quality pediatric practice.	36	43	15	5	1
Efficacy					
Preventive mental health interventions are generally worth the amount of time they take.	40	40	16	3	0
Preventive mental health sounds good as a concept, but in reality there is little evidence that preventive interventions are effective.	2	11	25	41	20
Ethics					
Attempting to intervene in the lives of the children of a psychiatric patient poses a serious ethical problem.	3	12	15	41	29
Preventive mental health efforts initiated by a pediatrician are potentially unethical because they are too intrusive.	1	1	7	37	54
Financial Barriers					
Most people at the present time are not very willing to pay for most preventive mental health interventions.	27	48	10	12	27
Third-party payers are not very likely to support reimbursement for preventive mental health interventions.	40	34	19	6	2
Educational/Time Barriers					
Pediatricians often find it difficult to initiate many preventive mental health measures because they are not trained to do so.	27	57	4	9	4
Pediatricians rarely have time to be concerned about the mental health of their patients.	5	27	9	40	19

Intercorrelations Among Scales and Barriers

Pearson correlation coefficients were calculated among the scales measuring attitudes toward prevention and barriers inhibiting preventive practice. All three attitudes toward prevention scales were positively correlated with each other ($P < .05$ to $P < .001$). Attitudes regarding financial barriers were negatively related to attitudes regarding the appropriateness of mental illness prevention ($P < .01$) but were unrelated to attitudes regarding the ethics or efficacy of mental illness prevention. That is, pediatricians who viewed mental illness prevention as less appropriate were more likely to feel that cost factors inhibited preventive mental health practice. Attitudes regarding educational and time barriers were positively related to attitudes regarding efficacy ($P < .02$), ethics ($P < .001$), and fi-

nancial barriers ($P < .001$). That is, pediatricians who perceived educational and time barriers as being more operative were also more likely to perceive financial barriers to mental illness prevention, but were also more likely to feel that such interventions were both effective and ethical.

Attitudes Toward Prevention and Pediatricians' Sociodemographic and Work Characteristics

Based on Pearson correlation coefficients and/or one-way analysis of variance, we found few relationships among scores on any of the five attitude and barrier scales with respondents' sex, race, religious affiliation, the amount or kind of course work they took before medical school, the number of hours they worked in an average week, or the number of journals they regularly read in an average month. Female pediatricians were slightly more likely than

male pediatricians to perceive mental illness interventions as appropriate ($\chi = 4.27 \pm 0.47$ vs 4.12 ± 0.44 ; 1 *df*; $F = 8.30$; $P < .004$). Academic pediatricians ($\chi = 3.35$) were less likely to perceive such interventions to be efficacious than house staff ($\chi = 3.55$) or clinical faculty ($\chi = 3.60$) (2 *df*; $F = 4.86$; $P < .008$).

Those pediatricians who had taken more humanities courses in college were more likely to perceive mental health-oriented prevention as role appropriate ($r = .154$; $P < .01$) and those reporting longer work weeks were a little less likely to see such interventions as efficacious ($r = -.147$; $P < .001$).

In looking at the relationship between career aspirations and attitudes toward prevention, only a few significant correlations were found. Pediatricians who were in or who aspired to careers in public health were a bit more likely to view mental health-oriented

prevention as role appropriate ($r = .154$; $P < .01$) and efficacious ($r = .133$; $P < .03$), and those who were in or aspired to a teaching affiliation were significantly more likely to feel that mental health-oriented prevention was appropriate ($r = .186$; $P < .001$). In contrast, pediatricians more likely to be in or aspire to a tenure track academic career felt that prevention was less efficacious ($r = .151$; $P < .01$).

Attitudes Toward Mental Health-Oriented Prevention and Personal Health Beliefs

Pediatricians answered 19 items constituting three scales that measured different dimensions of their beliefs about the locus of control in health matters: the role of chance, the general threat of serious disease, and the role of self-control and self-care. On these scales, higher scores indicated stronger beliefs in internal vs external factors (ie, a lesser role of chance and of serious disease as a threat to health and the greater importance of self-care).

In looking at the relationship between these health belief scale scores and our pediatricians' attitudes toward prevention, pediatricians who expressed more positive attitudes toward the efficacy of mental health-oriented prevention in their clinical practice were less likely to believe in the role of luck or chance in good health ($r = .22$; $P < .001$), less likely to view good health as seriously threatened by disease ($r = .15$; $P < .01$), and more likely to favor self-care ($r = .26$; $P < .001$). A favorable attitude toward the appropriateness of mental health-oriented prevention in clinical practice was also positively related to the importance of self-care ($r = .19$; $P < .001$).

COMMENT

Because our sample was drawn from a single medical school's pediatrics department, rather than from a broader community sample of practicing pediatricians, our response rate was only 70%, and the study relied entirely on self-report questionnaire measures, our results must be considered preliminary and may not be generalizable to all pediatricians. However, with these caveats

in mind, given that between 3% and 10% of patients under the age of 18 years are diagnosed in outpatient settings as having some type of mental disorder,⁷ it is encouraging that our sample of pediatricians expressed generally favorable attitudes toward the appropriateness, efficacy, and ethical nature of mental illness prevention in their practices. However, they also expressed significant uncertainty about the adequacy of the data on which the literature is based, and considerable concern that educational, financial, social, and organizational barriers had inhibited the growth of preventive mental health-oriented practices in pediatrics. Although we can be reassured that these pediatricians endorsed such prevention so favorably, additional studies of other groups of pediatricians are needed to determine the extent to which our preliminary findings can be generalized. The extent to which such positive attitudes are sufficient to actually overcome the numerous barriers that pediatricians also perceived is unknown. Studies relating the attitudes we studied to actual practice patterns are necessary to answer this question, especially since several recent studies conducted in primary medical care settings revealed that appropriate preventive care fell significantly short of generally agreed-on standards.⁸⁻¹⁰

Although many of the factors that we studied in relationship to attitudes toward mental illness prevention yielded weak, inconsistent, or no associations, several consistent trends in the findings are noteworthy. The significant associations between pediatricians' preventive practice orientations and their own personal health beliefs, previous interest in the humanities, and work habits suggest that prevention is one area in which personal beliefs may affect the practice behaviors or behavioral intentions of physicians. Only a few recent studies have explored the relationships between health beliefs and practice patterns in physician populations.¹¹ These findings may imply that before some pediatricians can be expected to change their practice patterns, they might have to undergo significant changes in their personal beliefs regarding how people

get sick or stay healthy. Such pediatricians may be identifiable on the basis of their personal beliefs about how one becomes and stays healthy.

Finally, another implication of our findings is that there needs to be a significant expansion of training activities directed toward increasing the knowledge and skills of medical students and residents related to mental health-oriented services,¹² an area of training in which most pediatricians believe they have received inadequate preparation.¹³

Advising Parents to Stop Smoking

Opportunities and Barriers in Pediatric Practice

Barbara L. Frankowski, MD, Roger H. Secker-Walker, MB

• All pediatricians in Maine were surveyed by mail to assess their beliefs and attitudes about parental smoking and their current activities concerning advice on smoking cessation. The response rate to three mailings was 86%. Most pediatricians (91%) reported advising parents who smoke to quit and estimated spending an average of almost 5 minutes giving advice on how to quit smoking. Almost all pediatricians (94%) felt moderately or very confident in addressing passive smoking issues. However, only 46% felt moderately or very confident in advising parents how to stop smoking. Important barriers to providing advice on smoking cessation to parents included negative parental expectations and not having enough time. Only 6% of the pediatricians noted lack of reimbursement as a barrier. The majority of respondents (84%) were moderately or very willing to learn brief methods of giving advice on how to stop smoking to parents.

(AJDC. 1989;143:1091-1094)

The Surgeon General has suggested that one of the pediatrician's most important educational obligations is to encourage and help parents give up cigarette smoking.¹ Pediatricians are in a unique position to address the issues of smoking prevention and smoking cessation at several levels. Healthy young adults who are starting a family see a pediatrician more often than any other health care professional. Of the 3.6 to 3.7 million women who have given birth in the United States each year since 1980, approximately 1.0 to 1.2 million women smoked while pregnant.² In addition, the majority of women who give up smoking during pregnancy start

smoking again after the baby is born.³ New parents are motivated to make changes in their own life-styles "for the good of the baby." The pediatrician usually sees the mother shortly before and after delivery of the baby and at regular intervals over the next few weeks, months, and years for health supervision and other visits. Each of these contacts could provide an opportunity to support a smoker in her efforts to quit or to support a recent ex-smoker in her efforts to refrain from starting again. Women who succeed in staying away from cigarettes will then model non-smoking behavior for their children.

The purpose of this study was to assess the current activities of pediatricians concerning their provision of smoking cessation advice for the parents of the children in their office practices, their beliefs and attitudes about the effects of passive smoking and the initiation of smoking in children and adolescents, their confidence in their ability to offer advice about smoking, the opportunities and perceived barriers to providing advice to stop smoking, and their willingness to learn methods of providing advice about smoking prevention and smoking cessation.

SUBJECTS AND METHODS

A questionnaire was developed to address the factors that might influence pediatricians to provide advice on smoking cessation to the parents of their pediatric patients. The questionnaire contained 50 items and addressed the pediatrician's estimate of the proportion of smoking parents with whom smoking is discussed, the pediatrician's concerns about parental smoking, their level of confidence in discussing the effects of parental smoking on children, the estimated proportion of parents advised to stop smoking and the time spent advising parents about quitting, their level of confidence in advising parents how to quit, and their level of willingness to learn brief methods of providing advice on smoking ces-

sation to parents. Further items addressed whether the office had a policy on smoking, the availability in the office of printed materials about smoking cessation, and a list of the available smoking cessation resources within the community. Additional questionnaire items addressed the perceived barriers to giving advice to parents who smoke, beliefs about the effects of parental smoking on children, and the opportunities pediatricians have to address the smoking issue with parents. Final questions inquired about smoking status, year of graduation from medical school, number of years in pediatric practice, pediatric subspecialty, and type of practice.

We pretested this survey instrument among the pediatric faculty at the Maine Medical Center, Portland, mailing the questionnaire to the pediatricians there and obtaining a response rate of 93%. After reviewing these responses, we surveyed all the remaining licensed pediatricians in the state of Maine using the same instrument. Second and third mailings were sent to non-respondents.

We examined the frequency of responses to each item and also the relationships among responses. For the items addressing attitudes toward the effects of parental smoking and the ratings of opportunities to advise parents to stop smoking, we devised simple scales by summing the responses to these items. Because most of these data are categorical, we used χ^2 analyses to identify significant relationships using a $P < .05$ as the level of statistical significance. For continuous variables, we grouped the responses into categories for comparison with the categorical responses.

RESULTS

In 1987, we mailed the questionnaire to 155 pediatricians and received 139 responses for a return rate of 89.7%. We excluded physicians who had retired ($n=16$), who reported they were no longer practicing in Maine, or who were in research or administration ($n=23$). With these exclusions, we had 100 respondents. We have assumed that the 16 nonrespondents were in active prac-

Accepted for publication March 29, 1989.

Reprint requests to Department of Pediatrics, University of Vermont School of Medicine, 1 S Prospect St, Burlington, VT 05401 (Dr Frankowski).

tice in Maine, for a response rate of 86.2% (100/116).

Pediatricians

On average, the respondent pediatricians, 34% of whom were women, had been in practice for 11.7 years (range, 1 to 40 years). Forty-six percent were in solo practice, 25% were in a partnership, 12% were hospital based, 7% were in group practices, 2% were in a community health center, and 8% were in other types of practice; 33% of all the respondents were on the faculty at the Maine Medical Center. Although 41% of the pediatricians had a subspecialty in pediatrics, the majority of these (74%) also saw patients for general pediatric problems. Only 4% were current smokers, 30% were former smokers, and 66% had never smoked.

Attitudes and Beliefs

Most pediatricians agreed or strongly agreed that parental smoking led to more respiratory infections (98%) and more ear infections (68%) in children and increased the chances that children will become smokers (94%). Many (65%) agreed that advice about smoking should be given to parents who smoke even when they bring their child to the pediatrician for problems unrelated to smoking.

Current Activities

Pediatricians' estimates of the proportion of parents who smoke ranged from about 10% to 50% or more, with the majority (72%) of respondents' estimates being about 25% or 33%. Most pediatricians (72%) estimated that they talk to 25% or more of the parents who smoke about the effects of smoking on their children, with 43% talking to three fourths or more of these parents. The major concerns addressed by the pediatricians were lower birth weight, the health effects of passive smoking on infants, parental modeling of smoking, the effects on parental health, and smoking-related environmental hazards such as fires and burns.

Most pediatricians (91%) reported advising parents who smoke to quit, with two thirds of the pediatricians advising 75% or more of such parents to do so. The average estimated proportion of parents advised to quit was 71.2%

Characteristics	Sample Size	Moderately or Very Confident in Advising Parents to Stop Smoking, %
Rating of opportunities to provide advice to parents to stop smoking

* $P < .01$.

(SD = 39.8%). The estimated time spent advising parents to quit, for those pediatricians (89%) who provided such an estimate, averaged 4.9 minutes (SD = 4.6 minutes). Seventy-four percent of the respondents who advised parents to stop smoking did not provide an estimate of the effectiveness of their advice; for the 26 pediatricians who did, the estimated successful rate of cessation ranged from 1% to 75%, with a mode of 10%.

Almost all pediatricians (94%) felt moderately (43%) or very confident (51%) in addressing smoking issues with parents, but only 46% of pediatricians felt moderately (28%) or very confident (18%) in advising parents to quit. Most pediatricians (92%) had a "no smoking" policy in their offices; 31% had lists of available smoking cessation resources in the community, and 25% had printed materials to give smokers to help them quit.

Opportunities to Talk to Parents About Smoking

Pediatricians were asked to rate various types of visits as poor, fair, good, or excellent opportunities to talk to or advise parents who smoke about stopping the habit. Prenatal visits, health supervision visits, and visits for acute respiratory problems were rated as good or excellent opportunities by 83%, 77%, and 87% of the respondents, respectively. Visits to the mother at delivery and visits for other problems were rated as good or excellent opportunities by smaller proportions of pediatricians, 67% and 37%, respectively. Pediatricians who rated these potential oppor-

tunities more highly also reported advising a significantly greater proportion of parents to quit than those who rated them less highly ($P < .01$).

Barriers to Providing Advice About Smoking to Parents Who Smoke

Twenty-four percent of the pediatricians thought that parents who smoke do not expect this advice from their pediatrician, while "not having enough time" was noted as a barrier to giving advice on smoking cessation by 23% of the respondents. Some pediatricians were concerned that parents would get defensive and might even change pediatric practices if offered such advice. Ten percent of the respondents felt ill at ease about giving such advice and 6% considered lack of reimbursement to be a barrier. Only 3% of the pediatricians believed that the effects on the child were not serious enough to warrant giving advice on smoking cessation to parents, and a similar proportion believed that giving advice about smoking was none of their business.

One or more barriers were identified by 65% of pediatricians, and these respondents were significantly less likely to advise parents to stop smoking than were pediatricians who identified no barriers ($P < .01$). Pediatricians who identified "parents not expecting this advice" as a barrier also reported advising significantly fewer parents to quit smoking ($P = .02$).

Confidence in Advising Parents to Stop Smoking

ing, not checking any of the barriers to talking to parents about smoking, and not checking "parents do not expect me to give this sort of advice" were each associated with higher levels of confidence in advising parents to stop smoking ($P<.01$) (Table 1).

Willingness to Learn Brief Methods of Advice

The majority of respondents (84%) were either moderately (38%) or very (46%) willing to learn brief methods of giving advice about stopping smoking to parents. Pediatricians who had fewer years of experience in pediatric practice were more willing to learn methods of smoking cessation for parents as compared with more experienced pediatricians ($P<.02$). There was no difference in "willingness" based on the type of practice. Pediatricians who identified themselves as smokers or ex-smokers were less willing to learn brief methods of advice on smoking cessation for parents than were those who had never smoked ($P<.02$). The level of willingness of the pediatricians to learn brief methods of giving advice on smoking cessation to parents was significantly and directly related to their rating of the opportunities to talk to parents about stopping the habit ($P<.01$) and to not identifying any barriers to giving advice about smoking to parents who smoke ($P<.01$) (Table 2).

COMMENT

The results reported herein are based on a high response rate (86%) to the three mailings of the questionnaire and are thus reasonably representative of the pediatricians practicing in the state of Maine. The pediatricians' estimates of the proportion of parents who smoke whom they advised to stop should be interpreted with some caution. Self-reporting may overestimate the proportion of physicians who claim they advise patients to stop smoking,⁴ and we do not have information from the parents. Nevertheless, some important observations can be made.

A large proportion of pediatricians report talking to parents about the effects of smoking on their children, and their concerns about these effects reflect the literature on passive smoking and parental role modeling.⁵⁻⁹ The vast majority of pediatricians report advising most parents to stop smoking, with two thirds reporting advising 75% or more of such parents to stop. The pediatricians' estimates of the proportion of parents advised to stop smoking varied widely, but the mean value, 71.2%, is close to that reported by healthy smokers attending university-based outpatient clinics (58%)¹⁰ and by other patients (60%).¹¹

The average reported time spent advising parents to quit was almost 5 minutes, with a range of 1 to 20 minutes.

These estimates of the time spent talking about smoking are comparable with those reported by Iowa physicians (median, 5 minutes; range, 1 to 30 minutes) and to patients' reports of the number of minutes their physicians spent talking about smoking in medical settings.^{12,13}

Use of the prenatal visit, health supervision visits, and visits for respiratory problems, which pediatricians considered the best opportunities to talk to parents about stopping smoking, and providing self-help materials and lists of available community smoking cessation resources to smokers would encourage and assist parents in their efforts to quit.

Hughes and Kottke¹⁴ identified five major reasons for physicians failing to ask patients to quit—not believing the advice is worthwhile, not having the time to give advice, feeling that counseling is not a physician activity, not wanting to embarrass patients or discourage them from returning, and not realizing that advising patients to quit smoking can be simple. Of these potential barriers, the time concern was checked as a barrier by about one fourth of the respondent pediatricians. The perception that parents who smoke do not expect this advice from their pediatricians was also checked by about one fourth of the respondents. When other comparable concerns about potential parental responses to advice on smoking cessation, such as getting defensive or changing pediatric practices, are added to the perception of parents' lack of expectation, barriers of this kind were noted by 30% of the pediatricians. Only three of the pediatricians believed that the effects of smoking on the child were not serious enough to warrant giving advice on smoking cessation to parents. The pediatricians' report of the high proportion of parents given advice on smoking cessation and the time spent doing this indicate that the vast majority believe that giving advice to stop smoking is worthwhile. Similarly, only three pediatricians considered that giving advice about smoking was none of their business, indicating that the vast majority do consider that giving advice about smoking to parents is a pediatrician activity. We did not have an item addressing Hughes and Kottke's fifth reason for not giving advice to patients about quit-

ting smoking. We also have no information yet as to how smoking parents themselves feel about receiving advice on quitting smoking from their pediatricians.

Pediatricians reported high levels of confidence in talking to parents about the effects of smoking on their children but had less confidence in advising parents to quit. Surveys of other physicians have also noted low levels of confidence in providing advice on smoking cessation.¹⁵⁻¹⁷ Most pediatricians provided no estimate of the success rate of their advice to quit smoking, but for those who did, the modal estimate was 10%. Success rates of this order after physician-delivered advice on smoking cessation have been reported from a number of studies. In a recently reported meta-analysis of 39 trials of advice on smoking cessation or counseling carried out in physicians' offices, the average reported rate of quitting after 1 year in the intervention groups was 5.8% higher than that in the control groups.¹⁸ Even a sustained rate of quitting as low as 5%, as reported by Russell and colleagues¹⁹ in 1979 using brief (2-minute) advice on smoking cessation, supportive printed material and follow-up (which was more effective than brief advice alone, 3.3%), would produce a large number of those who quit if all primary care practitioners engaged in this behavior. It has been shown that persuading as few as 1 in 20 smokers to quit compares favorably in cost-effectiveness to treating individual patients for hypertension or hypercholesterolemia.²⁰

As might be expected, there were generally high levels of willingness to learn brief methods of providing advice on smoking cessation to parents. This high level of willingness by pediatricians to learn methods of giving advice on smoking cessation is consistent with other reports concerning interest by primary care physicians in acquiring skills to help patients change their behavior.^{4,21} The confidence of physicians about their abilities to help patients stop smoking can be increased if they are given support, such as physician training, referral information, monetary reimbursement, literature to hand out, or the ability to hire or train staff to help.¹⁶

Perry and Silvis²² stress that pediatricians need to learn the skills to promote

nonsmoking and to encourage attempts to quit by parents and adolescents. They also need to motivate themselves to use these skills. In designing workshops or in-office training for pediatricians to enhance their skills in providing advice on smoking cessation to parents, we see several areas that need addressing. The barrier of perceived negative parental expectations needs to be resolved by asking parents what they think about their pediatricians advising them to stop smoking. The advice or counseling clearly needs to be delivered in about 5 minutes but also must be presented in such a fashion that the process of quitting and staying away from cigarettes can be brought up at each visit, if necessary. The important components of advice on smoking cessation for use in office practice, which can be delivered in 3 to 5 minutes, have been described by several authors.^{11,19,20,23-25} Most importantly, such training sessions should involve modeling the advice either live or on videotape and role playing the type of advice that can be given with appropriate feedback. Such modeling and role playing substantially increase confidence in one's ability to undertake these new skills and increase the likelihood that such advice will be given. Pediatricians are in an excellent position to incorporate advice on smoking cessation for parents into routine care, and by enhancing their skills in providing such advice, they may contribute more effectively to the concerted effort to help smokers stop smoking.

This project was supported in part by grant CA22453 from the Public Health Service, National Cancer Institute, Bethesda, Md.

Paul Dymont, MD, helped us to carry out the initial survey among the Pediatric Faculty at the Maine Medical Center.

information on the following page.

6/89

BRIEF SUMMARY

VIST®

nastine fumarate) SYRUP 0.5 mg/5 ml
sent as clemastine fumarate 0.67 mg/5 ml)

INDICATIONS AND USAGE

ist® (clemastine fumarate) Syrup is indicated for the relief of symptoms associated with allergic rhinitis such as sneezing, rhinorrhea, pruritus and lacrimation. Tavist® (clemastine fumarate) Syrup is indicated for use in pediatric populations (ages 6 through 12) and adults (see **DOSAGE AND ADMINISTRATION**).

It should be noted that Tavist® (clemastine fumarate) is indicated for the relief of mild, uncomplicated allergic skin manifestations of urticaria and angioedema at the 2 mg dosage level.

CONTRAINDICATIONS

Antihistamines are contraindicated in patients hypersensitive to the drug or to other antihistamines of similar chemical structure. **PRECAUTIONS — Drug Interactions** in a complete package insert).

Antihistamines should not be used in newborn or premature infants. Because of the higher risk of antihistamines for infants and for newborns and prematures in particular, antihistamine therapy is contraindicated in nursing mothers (see **PRECAUTIONS — Nursing Mothers** in a complete package insert).

WARNINGS

Antihistamines should be used with considerable caution in patients with: narrow angle glaucoma, stenosing peptic ulcer, duodenal obstruction, symptomatic prostatic hypertrophy, bladder neck obstruction.

With CNS Depressants: Tavist® (clemastine fumarate) additive effects with alcohol and other CNS depressants (barbiturates, sedatives, tranquilizers, etc.).

In Activities Requiring Mental Alertness: Patients should be warned about engaging in activities requiring mental alertness such as driving a car or operating appliances, machinery.

In the Elderly (approximately 60 years or older): Antihistamines are more likely to cause dizziness, sedation, and anxiety in elderly patients.

ADVERSE REACTIONS

Most frequent adverse reactions are underlined:

Central Nervous System: Sedation, sleepiness, dizziness, disturbed nation, fatigue, confusion, restlessness, excitation, nervousness, tremor, irritability, insomnia, euphoria, paresthesia, dizziness, diplopia, vertigo, tinnitus, acute labyrinthitis, hyperreflexia, convulsions.

Gastrointestinal System: Epigastric distress, anorexia, nausea, vomiting, diarrhea, constipation.

Respiratory System: Thickening of bronchial secretions, wheezing, chest and wheezing, nasal stuffiness.

Cardiovascular System: Hypotension, headache, palpitations, tachycardia, extrasystoles.

Hematologic System: Hemolytic anemia, thrombocytopenia, leukocytosis.

Genitourinary System: Urinary frequency, difficult urination, urinary retention, early menses.

Other: Urticaria, drug rash, anaphylactic shock, photosensitivity, excessive perspiration, chills, dryness of mouth, nose, throat.

DOSAGE AND ADMINISTRATION

DOSAGE SHOULD BE INDIVIDUALIZED ACCORDING TO CLINICAL NEEDS AND RESPONSE OF THE PATIENT.

Indications: Children aged 6 to 12 years

Symptoms of Allergic Rhinitis — The starting dose is 1 teaspoonful (0.5 mg clemastine) twice daily. Since single doses of 2.25 mg clemastine were well tolerated by this age group, dosage may be increased as required, but not to exceed 2.25 mg clemastine daily (3 mg clemastine).

Urticaria and Angioedema — The starting dose is 2 teaspoonful (1 mg clemastine) twice daily, not to exceed 6 teaspoonful daily (3 mg clemastine).

Indications: Adults and Children 12 Years and Over

Symptoms of Allergic Rhinitis — The starting dose is 1 teaspoonful (1 mg clemastine) twice daily. Dosage may be increased as required, but not to exceed 12 teaspoonful daily (6 mg clemastine).

Urticaria and Angioedema — The starting dose is 4 teaspoonful (2 mg clemastine) twice daily, not to exceed 12 teaspoonful daily (6 mg clemastine).

HOW SUPPLIED

*** (clemastine fumarate) Syrup**

nastine 0.5 mg/5 ml (present as clemastine fumarate 0.67 mg/5 ml). A clear, colorless liquid with a citrus flavor, in 4 fl. oz. (NDC 0078-0222-31).

Radiological Case of the Month

Christina T. Giuliano, MD; Abraham Zerykier, MD; Jack O. Haller, MD (*Contributors*);
Beverly P. Wood, MD (*Section Editor*)

A 12-year-old Asian boy with a diagnosis of acute lymphocytic leukemia received induction chemotherapy with good response. One month later, during the intensification phase of his chemotherapy, he was admitted to the hospital for abdominal pain.

On physical examination he appeared to be in poor physical health with generalized abdominal tenderness. Abnormal laboratory values included an erythrocyte sedimentation rate of 66 mm/h, and elevated amylase, aspartate aminotransferase, and alkaline phosphatase levels. The patient continued to reach temperatures of 39.4°C, despite antibiotic therapy with cephalothin, gentamicin sulfate, and carbenicillin disodium. His condition deteriorated, and he was taken to the operating room for exploratory laparotomy following computed tomographic (Fig 1) and gallium 67 citrate (Fig 2) studies.

Figure 1.

Figure 2.

Accepted for publication October 20, 1988.

Contributed from the Department of Radiology, Downstate Medical Center (Drs Giuliano and Haller), and the Department of Pediatrics, The Long Island College Hospital (Dr Zerykier), Brooklyn, NY.

Pylephlebitis Secondary to Unsuspected Appendiceal Rupture

Fig 1.—Computed tomographic scan of the liver showing a low attenuation area (arrow) in the posterior right lobe of the liver.

Fig 2.—Gallium 67 citrate scan showing an area of increased uptake in the corresponding region of the liver (arrow).

On exploratory laparotomy, the patient was found to have a ruptured appendix with microabscess formation in both lobes of the liver (pylephlebitis), an unusual complication of appendicitis rarely seen in the current era of antibiotics.

One week prior to admission, the patient had completed a course of induction chemotherapy consisting of vincristine sulfate, L-asparaginase, intrathecal methotrexate sodium, and prednisone. Postoperatively, his course was uncomplicated and uneventful. He resumed chemotherapy following his release from the hospital and has had a complete remission of acute lymphocytic leukemia. He is currently doing well, with no evidence of disease.

Pylephlebitis may be caused by any primary inflammatory disease in which suppurative tissue is drained by portal vein tributaries. One may see it secondary to a variety of intra-abdominal inflammatory processes within the gastrointestinal tract (appendicitis), pancreatic or biliary system, spleen, umbilical vein of neonates, or urogenital tract. It is rare that foreign bodies puncturing viscera drained by the portal tree or that the portal vein or its branches directly may cause pylephlebitis.¹ The high mortality associated with hepatic abscess (50% overall, 80% when secondary to causes other than appendicitis) make it important to recognize the presence of pylephlebitis.²

Pathologically, thrombophlebitis occurs in the intra-abdominal vessels of an infected viscus. This may progress to involve the draining veins with thrombotic extension along the portal route. Bacteria reach the liver and subsequently the portal triads, which

become infected both within and around the lymphatics. Polymorphonuclear leukocyte invasion and cellular debris extend directly into the hepatic lobular parenchyma. The resulting pyogenic liver abscesses may be found in one or both hepatic lobes and may be solitary, be confluent, or consist of multiple small abscesses diffusely distributed. Ochsner et al³ described multiple abscesses in 45% of their patients. Balasegaram⁴ found these lesions to be five times more common in the right lobe as compared with the left. This distribution is postulated to be the result of blood flow, with the abscess localized to the lobe that receives drainage from the primary site of infection. The right lobe receives a greater volume of blood, also contributing to the higher frequency of abscess found there.⁴

Classically, these patients present with hyperpyrexia, abdominal pain, and malaise. A leukocytosis is often evident. However, as 30% of hepatic abscesses are seen in leukemic children receiving immunosuppressive chemotherapy, suspicion must be raised when these neutropenic patients develop fever that is unresponsive to antibiotics.⁵

The diagnostic workup begins with roentgenograms, which sometimes reveal right basilar pulmonary atelectasis, hepatomegaly, or air-fluid levels in an abscess cavity within the right upper quadrant.

A computed tomographic scan of the abdomen is useful to delineate focal lesions in the hepatic parenchyma. An abscess in the liver may be identified as a low-attenuation focus, with contrast-enhancing thick borders. Small microabscesses appear as multiple, diffuse, low-attenuation lesions. These

are more commonly seen in immunosuppressed patients.

The differential diagnosis for the appearance of this computed tomographic scan includes cysts, liver adenoma, focal nodular hyperplasia, and intrahepatic or subcapsular mucinous metastases from the colon or ovary. Loops of bowel adjacent to the liver may mimic the appearance of a hepatic abscess.

To further clarify the nature of the lesion, a ⁶⁷Ga citrate nuclear scan is useful. ⁶⁷Ga has a high avidity for localized pyogenic disease, with a detection rate of 90%, and is currently the agent of choice for imaging suppurative inflammatory disease.⁶

When severe pylephlebitis is suspected, ultrasonography is also a useful tool to evaluate the portal venous network. This has successfully identified (1) echogenic thrombus in the lumen of the portal vein; (2) the existence of portal vein collateral circulation; (3) enlargement of an already thrombosed vein; and (4) cavernous transformation of the portal vein.⁷

Growing up on a steady theophylline is an open-and-shut case

Sprinkled

Intact

Changing your patients from sprinkled to solid theophylline administration shouldn't mean changing their serum levels as well. With Slo-bid, you won't change a thing when your younger asthma patients are ready to switch to intact administration.

Slo-bid maintains steady theophylline levels when switching from sprinkled to solid administration¹

Mean Serum Theophylline Concentration in 14 Children Dosed With Slo-bid Sprinkled and Slo-bid Intact

Switching from Slo-bid sprinkled to Slo-bid intact causes virtually no change in serum levels. Since the release system doesn't change, theophylline performance with both forms is identical. There's no need to restabilize your patients when they switch to taking capsules. In addition, capsules are the dosage form more patients prefer to take.²

Keep your patients' theophylline levels steady. Start and stay with Slo-bid. It's the perfect theophylline system for asthma patients to grow up with.

Slo-bid™

(theophylline, anhydrous)

50 mg, 75 mg, 100 mg, 125 mg, 200 mg, and 300 mg

Gyrocaps®

Timed-Release Capsules

BRIEF SUMMARY

DESCRIPTION: Slo-bid™ Gyrocaps® contain 50 mg, 75 mg, 100 mg, 125 mg, 200 mg, or 300 mg theophylline, anhydrous in the form of long-acting beads within a dye-free hard gelatin capsule and are intended for oral administration. Slo-bid Gyrocaps can be administered with a 12-hour dosing interval for a majority of patients and a 24-hour dosing interval for selected patients (see DOSAGE AND ADMINISTRATION section in full prescribing information for description of appropriate patient population).

INDICATIONS AND USAGE: For relief and/or prevention of symptoms from asthma and reversible bronchospasm associated with chronic bronchitis and emphysema.

CONTRAINDICATIONS: Slo-bid is contraindicated in individuals who have shown hypersensitivity to any of the components of this product. It is also contraindicated in patients with active peptic ulcer disease and in individuals with underlying seizure disorders (unless receiving appropriate anticonvulsant medication).

WARNINGS: Serum levels above 20 µg/mL are rarely found after appropriate administration of the recommended doses. However, in individuals in whom theophylline plasma clearance is reduced for any reason, even conventional doses may result in increased serum levels and potential toxicity. Reduced theophylline clearance has been documented in the following readily identifiable groups: 1) patients with impaired renal or liver function; 2) patients over 55 years of age, particularly males and those with chronic lung disease; 3) those with cardiac failure from any cause; 4) patients with sustained high fever; 5) neonates and infants under 1 year of age; and 6) those patients taking certain drugs (see PRECAUTIONS, Drug Interactions). Frequently, such patients have markedly prolonged theophylline serum levels following discontinuation of the drug.

Reduction of dosage and laboratory monitoring is especially appropriate in the above individuals.

Serious side effects such as ventricular arrhythmias, convulsions, or even death may appear as the first sign of toxicity without any previous warning. Less serious signs of theophylline toxicity (i.e., nausea and restlessness) may occur frequently when initiating therapy but are usually transient; when such signs are persistent during maintenance therapy, they are often associated with serum concentrations above 20 µg/mL. Stated differently, *serious toxicity is not reliably preceded by less severe side effects.* A serum concentration measurement is the only reliable method of identifying a potential for life-threatening toxicity.

Many patients who require theophylline exhibit tachycardia due to their underlying disease process, so the cause/effect relationship to elevated serum theophylline concentrations may not be appreciated.

Theophylline products may cause dysrhythmia and/or worsen preexisting arrhythmias and any significant change in rate and/or rhythm warrants monitoring and further investigation.

Studies in laboratory animals (minipigs, rodents, and dogs) recorded the occurrence of cardiac arrhythmias and sudden death (with histologic evidence of myocardial necrosis) when beta agonists and methylxanthines were administered concurrently. The significance of these findings when applied to humans is currently unknown.

PRECAUTIONS: General: On the average, theophylline half-life is shorter in cigarette and marijuana smokers than in nonsmokers, but smokers can have half-lives as long as nonsmokers. Theophylline should not be administered concurrently with other xanthine preparations. Use with caution in patients with hypoxemia, hypertension or with a history of peptic ulcer. Theophylline may occasionally act as a local irritant to the GI tract, although GI symptoms are more commonly centrally mediated and associated with serum drug concentrations over 20 µg/mL.

Information for Patients:

The physician should reinforce the importance of taking only the prescribed dose at the prescribed time intervals. The patient should alert the physician if symptoms occur repeatedly, especially near the end of a dosing interval. When prescribing administration by the sprinkle method, details of the proper technique should be explained to the patient.

Laboratory Test: Serum levels should be monitored periodically to determine the theophylline levels associated with observed clinical response and to identify the potential for toxicity. For such measurements, the serum sample should be obtained at the time of peak concentration, approximately 5-9 hours after the morning dose. It is important that the patient has not missed or taken additional doses during the previous 48 hours and that dosing intervals have been reasonably equally spaced.

DOSE ADJUSTMENT BASED ON SERUM THEOPHYLLINE MEASUREMENTS WHEN THESE INSTRUCTIONS HAVE NOT BEEN FOLLOWED MAY RESULT IN RECOMMENDATIONS THAT PRESENT RISK OF TOXICITY TO THE PATIENT.

Drug Interactions:

Drug-Drug: Toxic synergism with ephedrine has been documented and may occur with some other sympathomimetic bronchodilators. In addition, the following drug interactions have been demonstrated:

Theophylline with:
Allopurinol (high dose)

Increased serum theophylline levels

Cimetidine

Increased serum theophylline levels

Erythromycin, Troleandomycin

Increased serum theophylline levels

Lithium carbonate

Increased renal excretion of lithium

Oral contraceptives

Increased serum theophylline levels

Phenytoin

Decreased theophylline and phenytoin serum levels

Rifampin

Decreased serum theophylline levels

Drug-Food: Taking Slo-bid immediately after a high-fat content meal such as 8 ounces whole milk, 2 fried eggs, 2 strips bacon, one bran muffin with butter, 2 ounces hash brown potatoes (about 789 calories, including approximately 49 gm of fat) may result in a decrease in the rate of absorption, but with no significant difference in the extent of absorption (see CLINICAL PHARMACOLOGY, Pharmacokinetics). The influence of the type and amount of other foods, as well as the time interval between drug and food, has not been studied.

Drug/Laboratory Test Interactions: Currently available analytic methods, including high-pressure liquid chromatography and immunoassay techniques, for measuring serum theophylline levels are specific. Metabolites and other drugs generally do not affect the results. Other new analytic methods are also now in use. The physician should be aware of the laboratory method used and whether other drugs will interfere with the assay for theophylline.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies have not been performed with theophylline.

Chromosome-breaking activity was detected in human cell cultures at concentrations of theophylline up to 50 times the therapeutic serum concentrations in humans. Theophylline was not mutagenic in the dominant lethal assay in male mice given theophylline intraperitoneally in doses up to 30 times the maximum daily human oral dose.

Studies to determine the effect on fertility have not been performed with theophylline.

Pregnancy: Pregnancy Category C—Animal reproduction studies have not been conducted with theophylline. It is also not known whether theophylline can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Theophylline should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Theophylline is distributed into breast milk and may cause irritability or other signs of toxicity in nursing infants. Because of the potential for serious adverse reactions in nursing infants from theophylline, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use:

Safety and effectiveness of Slo-bid Gyrocaps administered:

1. Every 24 hours in children under 12 years of age, have not been established.
2. Every 12 hours in children under 6 years of age, have not been established.

ADVERSE REACTIONS: The following adverse reactions have been observed, but there has not been enough systematic collection of data to support an estimate of their frequency. The most consistent adverse reactions are usually due to overdosage.

Gastrointestinal: nausea, vomiting, epigastric pain, hematemesis, diarrhea.

Central Nervous System: headaches, irritability, restlessness, insomnia, reflex hyperexcitability, muscle twitching, clonic and tonic generalized convulsions.

Cardiovascular: palpitation, tachycardia, extrasystoles, flushing, hypotension, circulatory failure, ventricular arrhythmias.

Respiratory: tachypnea

Renal: potentiation of diuresis.

Other: alopecia, hyperglycemia, inappropriate ADH syndrome, rash.

CAUTION: Federal (U.S.A.) law prohibits dispensing without prescription. Keep this and all medications out of the reach of children.

NOW SUPPLIED:

Slo-bid Gyrocaps are identified as follows:

50 mg—Clear (cap) and opaque white (body) capsule with 50 printed in red

75 mg—Opaque white (cap) and clear (body) capsule with 75 printed in red

100 mg—Clear capsule with 100 printed in red

125 mg—Opaque white (cap) and opaque white (body) capsule with 125 printed in red

200 mg—Opaque white (cap) and clear (body) capsule with 200 printed in red

300 mg—Opaque white capsule with 300 printed in red

Slo-bid Gyrocaps 50 mg are available in bottles of 100 (NDC 0075-0057-00), bottles of 1000 (NDC 0075-0057-99) and in unit dose 10 x 10 (NDC 0075-0057-62). Slo-bid Gyrocaps 75 mg are available in bottles of 100 (NDC 0075-1075-00), bottles of 1000 (NDC 0075-1075-99) and in unit dose 10 x 10 (NDC 0075-0057-62). Slo-bid Gyrocaps 100 mg are available in bottles of 100 (NDC 0075-0100-00), bottles of 1000 (NDC 0075-0100-99) and in unit dose 10 x 10 (NDC 0075-0100-62). Slo-bid Gyrocaps 125 mg are available in bottles of 100 (NDC 0075-1125-00), bottles of 1000 (NDC 0075-1125-99) and in unit dose 10 x 10 (NDC 0075-1125-62). Slo-bid Gyrocaps 200 mg are available in bottles of 100 (NDC 0075-0200-00), bottles of 1000 (NDC 0075-0200-99) and in unit dose 10 x 10 (NDC 0075-0200-62), and Slo-bid Gyrocaps 300 mg are available in bottles of 100 (NDC 0075-0300-00), bottles of 1000 (NDC 0075-0300-99) and in unit dose 10 x 10 (NDC 0075-0300-62), and are manufactured by:

Gastroesophageal Reflux to the Proximal Esophagus in Infants With Bronchopulmonary Dysplasia

Bruce D. Sindel, MD; M. Jeffrey Maisels, MB, BCh; Thomas V. N. Ballantine, MD

• **Recurrent aspiration after gastroesophageal reflux (GER) may contribute to the severity of chronic lung disease. If so, it should be possible to document acid reflux to the proximal esophagus. Using an esophageal pH probe placed at the level of the first or second thoracic vertebra, we evaluated GER in 14 infants with bronchopulmonary dysplasia (BPD) and 13 infants without BPD. The infants with BPD had significantly less GER, as measured by the percentage of time the pH was less than 4 ($3.26\% \pm 7.05\%$ vs $12.88\% \pm 15.27\%$ [mean \pm SD]), number of GER episodes per hour (0.46 ± 0.66 vs 1.35 ± 0.83), number of GER episodes lasting longer than 5 minutes per hour (0.10 ± 0.23 vs 0.31 ± 0.29), and longest GER episode (6.76 ± 10.29 vs 26.66 ± 38.30 minutes). Gastroesophageal reflux may be unimportant in infants with BPD, or even occasional episodes of GER may aggravate existing lung disease.**

(AJDC. 1989;143:1103-1106)

Gastroesophageal reflux (GER) has been implicated as a contributing factor in a variety of respiratory diseases in infants, including apnea,^{1,3} recurrent pneumonia,^{4,5} asthma,^{6,8} and bronchitis.^{9,10} Although the mechanism is unclear, it is most likely recurrent aspiration of refluxed material or reflex bronchospasm mediated by chemoreceptors in the esophagus, larynx, or trachea.

Infants with bronchopulmonary dysplasia (BPD) are often examined and treated empirically for GER, although there are no data documenting the inci-

dence of GER in these infants. Three recent reports¹¹⁻¹³ suggest that antireflux therapy might produce improvement in infants with BPD. We therefore studied a group of infants with BPD to determine the frequency of GER to the proximal esophagus, and we compared them with a group of infants without BPD.

PATIENTS AND METHODS

Patient Population

Infants with BPD diagnosed from March 1984 through January 1985 were eligible for the study. The diagnosis of BPD was made in infants who had severe lung disease, who required mechanical ventilation for more than 2 weeks or oxygen therapy for more than 1 month, and in whom the typical chest roentgenographic changes were present.¹⁴⁻¹⁷ We selected only those with moderate to severe disease (as defined by the necessity for mechanical ventilation for longer than 30 days or oxygen therapy for longer than 40 days) since we believed that GER was more likely to contribute to the severity of lung disease in such infants.

Fourteen infants met these criteria, and all manifested one or more of the following: (1) vomiting, (2) extreme irritability, (3) recurrent cyanotic episodes resembling aspiration, (4) deterioration of respiratory status during enteral feeding, and (5) stable or worsening respiratory status in the face of adequate energy intake and growth. Eight of these infants received mechanical ventilation and two of the eight were studied twice, once during ventilation and once while breathing spontaneously. All infants received ventilation through orotracheal tubes, and none received nasal continuous positive airway pressure during these studies. All infants received approximately 150 mL/kg of fluid per day. Infants receiving mechanical ventilation were fed 50% to 100% of this volume via an indwelling nasogastric tube. Feedings were given every 3 hours in volumes ranging from 9 to 19 mL/kg per feeding (depending on the volume tolerated) to all infants who were not receiving ventilator therapy.

The comparison group consisted of 12 infants who were being studied (on clinical indication) for episodes of apnea and bradycardia and one growing premature infant. These infants were studied with a four-channel thermister pneumocardiogram and an esophageal pH probe. They were all stable and free of respiratory symptoms (other than apnea) at the time of the study. They were not vomiting excessively and were free of conditions believed to increase GER, such as excessive vomiting, severe central nervous system insults, methylxanthine therapy, or feeding via nasogastric tube.

Patient data are provided in Table 1. Since BPD is more common in extremely premature and very-low-birth-weight infants, it is not surprising that the birth weight and gestational age were much lower in the BPD group. Infants with BPD were also older at the time of the study, although the mean postconceptual age was similar in the two groups.

The study was approved by the Clinical Investigation Committee of The Milton S. Hershey Medical Center, Hershey, Pa, and informed parental consent was obtained in the case of the growing premature infant.

pH Studies

We monitored upper esophageal pH continuously in all patients by means of an esophageal pH probe (Microelectrodes Inc 508, Londonderry, NH) with a diameter of 1.4 mm. Before each study, the probe was standardized at a pH of 2 and 7 then inserted nasally and positioned in the stomach to document that the gastric pH was less than 4.0 (which it was in all cases). The probe was then placed in the proximal esophagus at the level of T1-2, and the position was confirmed by roentgenograms (Figure). The standardization at a pH of 2 and 7 was repeated at the completion of each study, and drift of more than 0.3 pH units was cause for rejection of the study. This occurred only once, and the study was repeated the next day without incident.

In preliminary studies we found that infant formula and human breast milk will buffer gastric acid, raising the pH to more than 4.0

Accepted for publication April 20, 1989.

Chest roentgenogram showing pH probe in the proximal esophagus at the level of the second thoracic vertebra.

for up to 2.5 hours after a feeding. We therefore fed infants dextrose water during the study to maintain gastric acidity. Infants were studied supine. A few of the infants with BPD receiving assisted ventilation were temporarily placed in the prone position when deterioration in color or blood gases occurred (usually after chest physical therapy). They were returned to the supine position as soon as they were stable. Infants were studied for periods of 6 to 14 hours (long enough to include at least two feedings¹⁸; the duration of most studies was 12 hours). All data were recorded continuously on a recorder (Gould 2400) or a computer (Hewlett-Packard 9845B, Palo Alto, Calif) and analyzed by one of us (B.D.S.). A reflux episode was defined as a pH of less than 4 for at least 15 seconds. Esophageal acid clearance time (or average length of each GER episode) was calculated by dividing the total time of pH less than 4 by the number of reflux episodes. The data were not normally distributed and were analyzed by means of the Mann-Whitney *U* Test.

RESULTS

Reflux data are shown in Table 2. Infants with BPD had significantly less GER than did infants without BPD when measured by percentage of time pH was less than 4 ($P < .05$), number of

GER episodes per hour ($P < .01$), number of GER episodes longer than 5 minutes per hour ($P < .025$), and longest GER episode ($P < .05$). The value for esophageal acid clearance time was also lower in infants with BPD but was not significantly different ($P < .1$).

The effect of mechanical ventilation on the BPD group is shown in Table 3. Two of these infants were studied twice, once while receiving mechanical ventilation and once while breathing spontaneously. Although no significant differences were found, there was a consistent trend toward less GER in all measurements in infants who were being mechanically ventilated.

COMMENT

Although the pathogenesis of GER in association with respiratory diseases is unclear, several mechanisms have been proposed. The bulk of the data points to a stimulation of the laryngeal or tracheal chemoreceptors by refluxed stomach contents, causing a reflex bronchospasm or laryngospasm. Previous studies by Johnson and others^{19,21} have demonstrated the existence of taste bud-like laryngeal chemoreceptors in fetal lambs and newborn human infants. These studies demonstrate a "diving reflex" (laryngospasm, bradycardia, and redistribution of blood flow in favor of the brain, heart, and adrenals) in fetal animals when the laryngeal area is exposed to water or heterologous milk.

There is some evidence of existence of this "laryngeal chemoreflex" in human preterm infants with apnea.²² A recent study by Tuchman et al²³ demonstrated a significant increase in total lung resistance in adult cats after an infusion of a tiny amount of acid into the trachea. A similar response, although much smaller quantitatively, was produced by much larger acid infusion into the esoph-

agus. The authors postulated that "microaspiration in the trachea is a much more likely mechanism for bronchospasm associated with GER than simple acid-reflux into the esophagus." Herbst et al¹¹ were able to induce obstructive apnea in infants with BPD and apnea by instilling acid into the midesophagus. They also postulated that stimulation of laryngeal or pharyngeal chemoreceptors was the mechanism for the reflex laryngospasm. These data seem to implicate GER in the midesophagus as an important factor in the genesis of GER-associated respiratory disease.

Gastroesophageal reflux to the upper esophagus has been documented in infants with recurrent pneumonia,²⁴ while other studies have failed to find any correlation between GER as measured in the lower esophagus and respiratory disease²⁵ or apnea.²⁶ By means of extended lower esophageal pH monitoring, it has been shown that respiratory symptoms are associated with an increase in the mean duration of reflux (or esophageal clearance time) during sleep.²⁷ One could postulate that poor esophageal clearance while the subject is sleeping, and often supine, would likely cause the refluxed acid to reach the upper esophagus, larynx, or pharynx. We therefore decided to perform all of our pH studies in the upper third of esophagus.

Some clinicians have suggested that GER may contribute to the severity of chronic lung disease, although evidence of this is limited. We recently reported our experience in 10 infants with BPD who underwent antireflux surgery.¹² After surgery, 4 of the 5 infants receiving mechanical ventilation were weaned from it, and an additional 4 infants were weaned from oxygen therapy. The mean PCO₂ also decreased by 10 mm Hg. Herbst and coworkers¹¹ studied 14 infants with BPD who were found to have GER confirmed by barium esophagogram and the Tuttle test. Although they used apnea as a measure of illness in these infants, all infants required oxygen and 3 were being mechanically ventilated when antireflux therapy was initiated. By the end of 1 week, the apnea had improved, no patient was receiving ventilation therapy, and only 3 of 14 required oxygen. Our infants with BPD were generally sicker than those stud-

*GER indicates gastroesophageal reflux; BPD, bronchopulmonary dysplasia.

†Fourteen infants were studied; 2 were studied both with and without mechanical ventilation.

ied by Herbst et al. Eight of the 14 infants we studied were being mechanically ventilated (and therefore not having apnea), and all of the infants had higher oxygen requirements than those in the previous report. However, we did not specifically record the number of apneic episodes per day in our infants.

Our infants with BPD had significantly less GER than did those without BPD. This finding is surprising, but it could be explained by several factors: Boix-Ochoa and Canals²⁸ showed that there is a maturational process involving the lower esophageal sphincter and that this is primarily dependent on chronologic age, but not on postconceptional age. (Mean age of the infants with BPD was 72.9 days vs 34.4 days for those without BPD.) Mechanical ventilation might affect lower esophageal sphincter

tone. As shown in Table 3, there was a trend toward less GER in infants receiving ventilation, although, due to the small sample size, the differences were not significant. Even the infants with BPD who were not receiving ventilation (Table 3), however, had less GER than did the infants without BPD (Table 2). A third possible explanation is the effect of increased strength and frequency of diaphragmatic contractions on lower esophageal sphincter tone. A recent study demonstrated that the normal oscillation of the lower esophageal sphincter pressure seen during respirations is due to diaphragmatic contractions, and lower esophageal sphincter pressure will increase with increased force of contraction of the diaphragm.²⁹ This effect can be explained anatomically by the way the crura fibers of the diaphragm

wrap around the lower esophageal sphincter, forming a "sling." As infants with BPD are usually tachypneic and/or hyperpneic, the increased diaphragmatic contractions may play a role in decreasing GER in these patients.

We found it impossible to obtain matched controls for the infants with BPD. Infants without BPD are rarely hospitalized for a prolonged period, and we could not obtain consent for the study of otherwise well infants who were already discharged. Therefore, we believed that the best (available) infants for comparison were those in our convalescent nursery who were having no problems other than apnea. However, this group of infants was similar to the infants with BPD in postconceptional age only and cannot be considered true controls.

The degree of GER found in this group of infants was surprising. All were asymptomatic except for apnea, and multichannel recordings did not demonstrate an association between GER and apnea. On follow-up, all of these infants were normal and growing well.

We believe that the diagnosis of "pathologic" GER can be excluded on clinical grounds. The amount of GER observed in these growing premature infants, therefore, either is normal or is related to some other factor.

Currently, there are no published normal data on GER in growing premature infants as measured by a pH probe in the upper esophagus. There is only one study of normal values for GER to the lower esophagus measured with a pH probe. Herbst et al¹¹ studied 14 hospitalized infants less than 6 weeks old and found that, although some of the neonates had mildly elevated scores, they did not differ significantly from those of older children. These infants were studied with the use of standard feeds and in all positions. The scores were based on measurements obtained more than 2 hours after feeding (this has been found to help identify symptomatic GER in older infants²⁶). These technical factors may explain the differences in GER found in growing premature infants in the two studies.

We studied our infants supine; they were fed dextrose water, and the data reported are those for the entire 6- to

12-hour study. We found that infant formulas will buffer gastric acid, raising the pH to levels above 4.0 for up to 2.5 hours after feeding. Thus, reflux of gastric contents during this period will not lower the esophageal pH. Sondheimer¹⁸ used a pH probe to monitor GER in infants who received alternating feedings of cows'-milk formula and apple juice (which is similar to dextrose water). She found more GER after a feeding of apple juice than after the cows'-milk formula. Although it is possible that an "acidic" feeding might exacerbate GER, Sondheimer thought (as we do) that this is unlikely. It is more likely that the apparent increase in GER (after ingestion of apple juice) resulted from the buffering effect of cows' milk. Because growing premature infants are fed every 2 to 4 hours, restricting observations to a period longer than 2

hours after a feeding will eliminate most of the day's data from the evaluation and much of the GER detectable in these infants. Methodologic differences could account for the discrepancy between our infants and those described by Herbst et al.¹¹ There is an urgent need for more studies of a growing neonatal population to establish normal values for GER in both the upper and lower esophagus.

There are obvious hazards in attempting to draw conclusions from this small descriptive study. The small sample size can lead to type I as well as type II errors.³⁰ However, the infrequent GER found in infants with BPD is perplexing. If GER contributes to the severity of the pulmonary disease in these infants, then aspiration after infrequent episodes of reflux may be sufficient to aggravate existing lung disease. Alter-

natively, GER may produce bronchospasm as a result of a vagal reflex from acid in the distal esophagus. This would not be recorded by a proximal pH probe. Monitoring proximal and distal esophageal pH simultaneously, together with transcutaneous P_{O_2} and PCO_2 , would document changes in respiratory status associated with GER in these infants. Such information might shed more light on the role of GER in chronic lung disease. Our data and those of Giuffre et al.¹³ suggest, however, that in selected cases (and by whatever mechanism) GER is a significant problem in BPD and that these infants may show a dramatic response to fundoplication.

We greatly appreciate the assistance of Kimberly Law and Janalee Baughman in the preparation of the manuscript.

Postdelivery Head Bleeding in Hemophilic Neonates

Causes and Management

Morris Kletzel, MD; Connie H. Miller, PhD; David L. Becton, MD; William M. Chadduck, MD; Joseph M. Elser, MD

• During a 12-month period, four of the five infants with hemophilia known to have been born in Arkansas were examined for head bleeding. Three of the infants had had traumatic delivery, with use of low forceps in two and vacuum extraction in one. In the fourth patient, hemophilia was prenatally diagnosed, and vaginal delivery resulted in cephalohematoma. Diagnosis was delayed in three patients, including one with a family history of hemophilia. Central nervous system bleeding may be more common in hemophilic neonates than has been presumed. Pregnancy management should include consideration of family history of bleeding disorders and carrier testing in appropriate cases. In confirmed carriers, prenatal diagnosis is justified to allow choice of the least traumatic delivery method. Any term neonate with intracranial hemorrhage should be treated as being possibly hemophilic until proved otherwise.

(AJDC. 1989;143:1107-1110)

Hemophilia is an X-linked coagulation disorder due to deficiency of factor VIII or factor IX, occurring in moderate or severe form in 1 of 8000 male births.¹ Two thirds of hemophiliacs are born to women with a family history of the disorder.² Availability of restriction fragment length polymorphism analysis has improved the accuracy of carrier detection and the safety of prenatal diagnosis, which can now be performed by chorionic villus sampling or amniocentesis rather than by fetal blood sampling in the majority of cases.³ Up to one half of hemophilia carriers elect prenatal di-

agnosis,² but termination of pregnancy is unacceptable to many.^{2,4} Therefore, delivery of an infant known to be at risk is not infrequent. Although intracranial hemorrhage is a leading cause of death in hemophiliacs, its occurrence in the neonate has been considered rare, with an incidence of 1% to 4%.⁵⁻⁷ Modification of delivery methods for potentially affected infants has not usually been recommended.^{8,9}

During a 12-month period, four of the five hemophiliacs known to have been born in the state of Arkansas were examined with signs of head bleeding, with one fatality. We describe these patients, with recommendations for appropriate management of at-risk pregnancies and the bleeding newborn.

PATIENT REPORTS

PATIENT 1.—A 4-day-old white boy had been born to a 28-year-old, gravida 1 woman at term by spontaneous vaginal delivery with the use of low forceps. He was circumcised on day 2, developing bleeding that was stopped with two sutures. Three days after discharge from the nursery, he was taken to the local emergency department with apneic spells. An evaluation to rule out sepsis was performed, and he was admitted to the local hospital and started on a regimen of broad-spectrum antibiotics. Because of a drop in hematocrit and oozing from venipuncture sites, he was given 10 mL/kg of fresh-frozen plasma (FFP) and packed red blood cells. A computed tomographic (CT) scan and ultrasound of the head revealed a large subdural hematoma, intracerebral hemorrhage, and marked cerebral edema (Fig 1). After administration of FFP, the patient's factor VIII level was 24%. He was then given cryoprecipitate. He became apneic and was intubated and transferred to Arkansas Children's Hospital, Little Rock.

On the patient's arrival, activated partial thromboplastin time (PTT) was 26.2 seconds (normal, 21.0 to 32.0 seconds), prothrombin time was 11.7 seconds (control, 12.0 sec-

onds), fibrin degradation products and platelet counts were normal, and no evidence of fragmented red blood cells was seen on smear. After neurosurgical evaluation, 5 mL of blood was removed from the posterior fossa. Cryoprecipitate treatment was continued, and normal results of coagulation studies were maintained. While receiving mechanical ventilation, the patient developed inappropriate secretion of antidiuretic hormone syndrome. A second CT scan revealed massive cerebral edema with complete loss of gray and white matter interface. An ultrasound scan of the head showed reverse flow into the cranium. Because of the devastating central nervous system injury, he died at 7 days of age.

Although there was no family history of coagulation disorders, the mother had low factor VIII levels on two occasions. Examination of six family members showed no other evidence of hemophilia or von Willebrand's disease. The mother's test results on two occasions indicated that she was a carrier of hemophilia (Table 1), confirming the diagnosis in the patient. The maternal grandmother's test results were inconclusive. DNA analysis was not attempted.

In a subsequent pregnancy, the parents elected prenatal diagnosis and were found to have a female fetus.

PATIENT 2.—A 4-day-old white boy had been born vaginally with low forceps at term to a gravida 1 mother. Membranes had ruptured 12 hours before delivery. The patient underwent circumcision on day 2 without complication. Twenty-four hours later, he returned to the local physician with persistent bleeding, and a suture was placed at the site of circumcision. At that time he was vomiting, for which his formula was changed.

Twenty-four hours later, the patient returned with persistent vomiting and lethargy. An evaluation to rule out sepsis was performed, and he was started on a regimen of ampicillin sodium and ceftriaxone sodium (Rocephin). His total bilirubin level was 513 $\mu\text{mol/L}$. He was then transferred to a regional hospital where he required intubation. His pupils were pinpoint, with a tense fontanelle. An ultrasound scan of the head showed evi-

Fig 1.—Computed tomographic scan of patient 1, without contrast, showing a posterior ossa interhemispheric subdural hematoma with subarachnoid hemorrhage and massive cerebral edema with more mass effect on the right than the left, with a midline shift.

Fig 2.—Computed tomographic scan of patient 2 showing a large hemorrhage involving the third ventricle with obstructive hydrocephalus. A small hemorrhage can also be detected in the lateral ventricle.

Table 1.—Hemophilia Carrier Test Results in Family of Patient 1

Relative	Factor VIII, %	vWF Antigen, %	Ratio of VIII/vWF
Mother	43	69	0.62
	24	55	0.44
Maternal grandmother	142	192	0.74
Maternal aunt	159	161	0.99
Normal range	50-200	50-200	>0.73 ¹¹

ence of an intracranial hemorrhage. Laboratory evaluation gave the following values: hemoglobin, 124 g/L; hematocrit, 0.36; platelet count, $354 \times 10^9/L$; glucose, 33.8 mmol/L; total bilirubin, 393.3 $\mu\text{mol/L}$; prothrombin time, 12 seconds (control, 12 seconds); PTT, 31 seconds (normal, 21.0 to 32.0 seconds); and factor VIII, 6%. He was given cryoprecipitate and transferred to our institution.

On the patient's arrival, a CT scan of the head was performed, revealing a large hemorrhage in the third ventricle, with obstructive hydrocephalus and a small hemorrhage in the lateral ventricle (Fig 2). Replacement therapy with factor VIII concentrate (Monolate, Armour Pharmaceutical Co, Tarrytown, NY) was started. The patient developed progressive hydrocephalus, and a ventriculoperitoneal shunt was placed on day 21. The patient continued to receive replacement therapy for 14 days, after which he was discharged.

The family history is unknown because the mother was adopted. After discharge, no bleeding problems occurred, and the result of factor VIII assay without replacement ther-

apy was less than 1%. Results of a neurodevelopmental assessment 3 months later were normal.

PATIENT 3.—A 2-day-old black boy had been born vaginally with vacuum extraction at 41 weeks of gestational age to a 23-year-old, gravida 2 mother. He was circumcised immediately after birth. On day 2 he was noted to have an increase in head circumference and pallor. Laboratory evaluation at that time revealed a hematocrit of 0.13, platelet count of $190 \times 10^9/L$, prothrombin time of 14.5 seconds, and PTT of 95 seconds. His mother was noted to have a family history of hemophilia.

The child immediately received FFP, packed red blood cells, and phytonadione and was transferred to our institution, where his head circumference was found to be at the 90th percentile, with a bulging fontanelle and a left cephalohematoma. A CT scan and ultrasound scan of the head failed to show an intracranial hemorrhage; all bleeding was localized in the subgaleal compartment. Laboratory evaluation on admission revealed a hematocrit of 0.19, prothrombin time of 12

seconds (control, 12 seconds), PTT of 35.2 seconds, factor VIII level of 29%, and factor IX level of 80%, after he had received FFP. He was given replacement therapy with factor VIII concentrate for an additional 7 days and showed a marked recovery. Factor VIII level without replacement was less than 1%. He had no neurologic sequelae.

The pedigree obtained by history is shown in Fig 3. A 3-year-old brother was unaffected.

PATIENT 4.—A 2-day-old white boy had been born at term by spontaneous vaginal delivery to a 26-year-old, gravida 3 mother, without complications during labor or delivery. Because she had a 2-year-old son with severe factor IX deficiency, the mother underwent prenatal diagnosis. DNA analysis of cells obtain amniocentesis indicated that this fetus also had factor IX deficiency.

At 8 hours of age, the infant was noted to have a progressively enlarging cephalohematoma and increasing lethargy. A CT scan and ultrasound scan failed to show intracranial hemorrhage. The diagnosis of factor IX deficiency was confirmed. The child received FFP and recovered from the initial episode. While receiving replacement therapy, he was circumcised without complications. On follow-up no sequelae were found.

COMMENT

Intracranial hemorrhage in the neonate with hemophilia is considered to be rare. A retrospective study⁶ of 71 patients with central nervous system bleeding among 2500 hemophiliacs found only 3 in the newborn period. More recently, review of records on 150 hemophiliacs found intracranial bleeding to be the initial sign in 8 patients, 5 of whom were less than 1 week of age.⁷ Our experience leads us to suggest that the incidence may be higher, since such retrospective studies include only those infants who survived until a diagnosis was made.

Among the 18 000 male births annually in Arkansas, 2.25 hemophilic newborns per year would be expected.¹ During a recent 12-month period, five hemophilic infants were known to have been born in the state. Arkansas Children's Hospital is the major referral hospital for children in the state and has the only hemophilia treatment program. Most hemophilic infants are therefore seen at our institution, and ascertainment is likely to be nearly complete. Four of the five infants with hemophilia had signs and symptoms of

Table 2.—Summary of Cases

Case No.	Factor Deficiency	Family History	Age at Diagnosis of Hemophilia, d	Type of Delivery	Presenting Symptoms	Outcome
1	VIII	Negative	4	Vaginal, forceps	Apneic spells	Dead
2	VIII	Negative	4½	Vaginal, forceps	Lethargy, vomiting	Alive, VP shunt
3	VIII	Cousin with hemophilia	2	Vaginal, vacuum	Increase in head circumference	Alive, no sequelae
4	IX	Brother with hemophilia	2	Vaginal	Increase in head circumference	Alive no sequelae

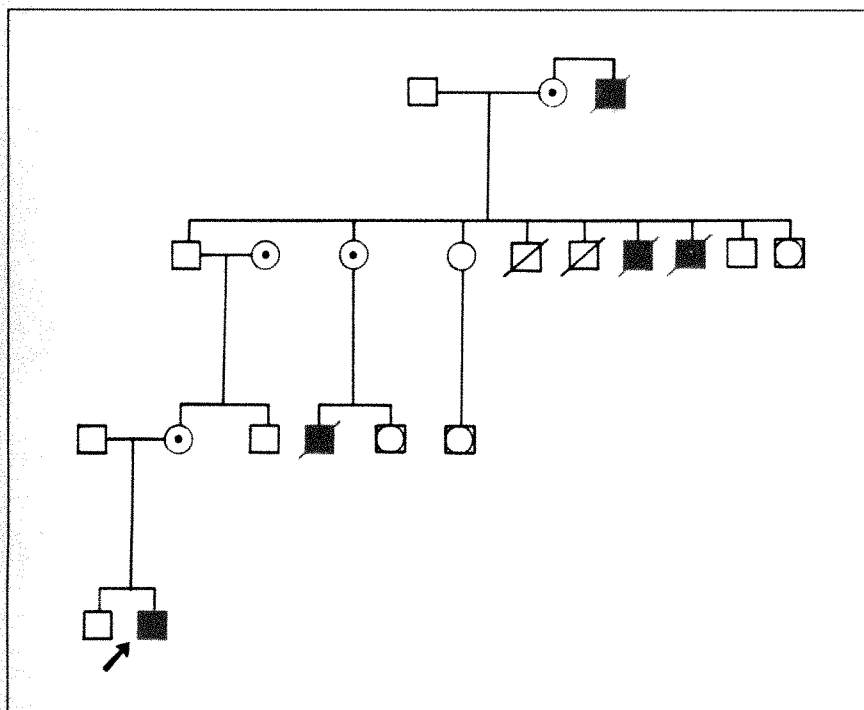

Fig 3.—Pedigree of patient 3 (arrow). Closed squares indicate patients with classic hemophilia; open circles with dot in center, hemophilia carrier.

head bleeding. The details of diagnosis, delivery, and outcome are summarized in Table 2. Two infants had intracranial hemorrhage, and one of those died. The common feature in three of the cases is traumatic delivery. Two of the patients were delivered with use of low forceps and one with vacuum extraction. For delivery of the fourth patient, whose condition had been diagnosed prenatally, use of cesarean section had been planned if difficulties arose, to avoid excessive head trauma. Vaginal delivery without intervention resulted in cephalohematoma. The association of intracranial bleeding with traumatic delivery was documented in three of the five newborns with intracranial hemorrhage described by Bray and Luban¹¹ and one of the five described by Yoffe and Bu-

chanan.⁷ Hemophilic infants are clearly at risk for head trauma under some delivery conditions.

Delay in recognition of the diagnosis undoubtedly contributed to morbidity and mortality in our patients. It is likely that the diagnosis could have been made 24 to 48 hours earlier if the index of suspicion had been higher. In the two patients without family history of hemophilia, sepsis was suspected initially; histories of bleeding from circumcision and traumatic delivery were ignored. As would be expected, appropriate treatment was initiated more rapidly in those infants with hemophilic relatives. However, patient 3, an at-risk infant, was not tested before circumcision and discharge from the local hospital. The long lag time between trauma and ap-

pearance of symptoms is typical of central nervous system bleeding in hemophiliacs.⁵ In these patients low hematocrit and/or prolonged PTT led to the performance of coagulation factor assays and appropriate replacement therapy before transfer to the tertiary care center. In no instance was neurosurgery performed without diagnosis, as has previously been reported.¹¹ Use of cryoprecipitate for treatment of factor VIII-deficient children was standard care in Arkansas until 1987 due to the low incidence of human immunodeficiency virus and hepatitis B infection.¹²

Intracranial hemorrhage is a common occurrence in the premature newborn. In the term infant, however, it should alert the pediatrician or neonatologist to the possible diagnosis of hemophilia. It has been suggested that full-term newborn boys with intracranial hemorrhage be considered hemophilic until proved otherwise.^{7,11}

From our experience and that of others, we draw the following conclusions:

1. Inquiry about personal and family history of bleeding disorders is crucial to appropriate delivery management for every pregnant woman and, since two thirds of hemophiliacs are born to women with family histories of the disorder,² will reveal the risk in the majority of cases.

2. When family history is present, pregnant potential carriers should be tested by coagulation studies or, preferably, DNA analysis to aid in management.

3. In women who are carriers of hemophilia, prenatal diagnosis by amniocentesis and DNA analysis, when possible, appears justified for management of a safe delivery. Risks of the procedure and various delivery options should be discussed with the patient.

4. If a bleeding disorder is suspected or is diagnosed prenatally, the least traumatic delivery method should be se-

lected to minimize the risk of intracranial hemorrhage, and a pediatrician or neonatologist familiar with hemophilia treatment should attend the birth. If presence of a bleeding disorder can be ruled out, the woman may be spared an unnecessary cesarean section.

5. Diagnosis of intracranial hemorrhage by ultrasound or CT scan in a term newborn should prompt intervention with replacement therapy with FFP until the diagnosis is known, to minimize the damage to the central nervous system. Specific factor replacement

should then follow with the appropriate concentrate in its most virus-free form.

We wish to thank Mary Jo Whaley and Jacquelyn Ford for assistance in collecting patient data and Flora Hawks for artwork.

CORRECTION

Incorrect Phrasing.—In the letter entitled "Interactions of Alcohol and Nutrition," published in the May issue of *AJDC* (1989;143:519), errors appeared in two places. In the second paragraph, second sentence, where the text reads "...for example, as well as the increased urinary excretion, . . ." the two words "for example," should be removed. In the fourth sentence of the same paragraph, where the text reads "... that this effect could explain increased . . .," the word "explain" should be replaced with "reflect."

Hypophosphatemia in the Nutritional Recovery Syndrome

Adam G. Mezoff, MD; David A. Gremse, MD; Michael K. Farrell, MD

• We studied the incidence of hypophosphatemia in patients during the nutritional recovery syndrome. The charts of 150 patients receiving a complete nutritional assessment for 18 months were reviewed; 45 met established nutritional risk criteria. Only 9 of these 45 had serial phosphorus values measured during nutritional repletion, and 5 of these 9 patients had hypophosphatemia (phosphorus levels <0.97 mmol/L). Anthropometric measurements of arm circumference and arm muscle circumference were less than the fifth percentile in all patients developing hypophosphatemia. We concluded that hypophosphatemia is an underrecognized complication of nutritional repletion and that anthropometric measurements may be predictive of patients at risk. All patients with significant malnutrition should be evaluated for this complication of refeeding.

(AJDC. 1989;143:1111-1112)

Hypophosphatemia is a significant complication of several conditions, including alcoholism, diabetic ketoacidosis, parenteral nutrition, severe respiratory alkalosis, chronic antacid therapy, and the recovery phase after severe burns. A significant cause of hypophosphatemia in children is the nutritional recovery syndrome, defined as a constellation of events occurring during the refeeding of significantly protein energy malnourished patients.¹ Prolonged hypophosphatemia may result in dysfunction of several different organ systems including hematologic, neurologic, and nephrologic.

We therefore sought to determine the incidence of hypophosphatemia in malnourished children as a complication of nutritional rehabilitation, to identify

clinical or biochemical risk factors for the development of hypophosphatemia in these children, and to review the major complications and treatment of this potentially fatal but eminently treatable condition.

PATIENTS AND METHODS

The medical records of all inpatients who underwent formal nutritional assessment at our institution from January 1, 1987, to June 1, 1988, were reviewed. In all patients, weight, length, and head circumference were measured according to the methods described by Jelliffe.² Weight/length index as well as ideal weight for length were calculated. Midarm muscle circumference, arm muscle area, midarm circumference, triceps skin-fold thickness, and subscapular skin-fold thickness were measured and used to estimate somatic protein stores and body fat composition.³⁻⁸ Visceral protein stores were estimated by retinol-binding protein, prealbumin, transferrin, and albumin determinations.^{9,10} Nutritional requirements were estimated by oxygen consumption testing.^{11,12}

We defined a malnourished patient as one whose nutritional assessment demonstrated at least one of the previously established nutritional risk criteria, and had a history and clinical findings compatible with protein energy malnutrition. These criteria included the following: height and weight less than the fifth percentile; muscle arm circumference less than 5%; albumin levels of less than 35 g/L; prealbumin and retinol-binding protein less than normal for age; weight/height index less than 90%; arm circumference and triceps skin-fold less than the fifth percentile; transferrin levels less than 2 g/L; and total lymphocyte count less than 1.5×10^9 /L.

Refeeding was defined as providing at least 75% of the patient's estimated energy needs for growth with demonstrable weight gain. Subjects were included in this study if serum phosphorus concentration was measured before refeeding, after the onset of refeeding, and serially thereafter. Hypophosphatemia was defined as a serum concentration of less than 0.97 mmol/L. Patients with underlying conditions that would interfere with phosphorus metabolism, absorption, or excretion were excluded. Patients whose serum phosphorus values did not return to normal after adequate supplementation were also excluded.

RESULTS

The medical records of 150 inpatients for whom adequate nutritional assessments were performed were reviewed. Their ages ranged from 6 months to 19 years. Of these 150 patients, 45 were malnourished by nutritional risk criteria and had no underlying condition that would affect phosphorus metabolism. The diagnoses of these patients included the following: failure to thrive ($n=12$), mental retardation/cerebral palsy ($n=9$), anorexia nervosa ($n=7$), juvenile rheumatoid arthritis ($n=3$), Crohn's disease ($n=3$), biliary atresia ($n=2$), cyanotic congenital heart disease ($n=2$), teratoma ($n=1$), apnea ($n=1$), tricyclic ingestion ($n=1$), scleroderma ($n=1$), meningitis ($n=1$), Niemann-Pick disease ($n=1$), and gunshot wound/pelvic osteomyelitis ($n=1$). Three of the patients with mental retardation/cerebral palsy, 1 of the patients with anorexia nervosa, and the patient with gunshot wound/pelvic osteomyelitis all were hypophosphatemic. The serum phosphorus concentration was measured in only 9 (20%) of these 45 patients during the initial part of their nutritional resuscitation.

Six episodes of hypophosphatemia occurred in five of these nine patients during renourishment. Two hypophosphatemic episodes resulted in serum phosphorus concentrations less than 0.32 mmol/L, two with concentrations between 0.32 and 0.64 mmol/L, and two episodes with concentrations between 0.64 and 0.97 mmol/L. The serum phosphorus concentration decreased in two patients within 24 hours of refeeding, and in all patients within 72 hours.

We analyzed all measurements and found that arm circumference and arm muscle circumference measurements were the nutritional risk factors predictive for all episodes of hypophosphatemia. Weight/height index and triceps skin-fold thickness met nutritional risk criteria in four of five patients with hypophosphatemia and are shown in the following tabulation:

Accepted for publication March 27, 1989.

From the Division of Gastroenterology and Nutrition, Children's Hospital Medical Center, Cincinnati, Ohio.

Reprint requests to Division of Gastroenterology and Nutrition, Children's Hospital Medical Center, Elland and Bethesda avenues, Cincinnati, OH 45229 (Dr Farrell).

Predictive Nutritional Measurements	No. of Patients With Abnormality/ Total No. of Hypophosphatemic Patients
Arm muscle circumference <5%	5/5
Arm circumference <5%	5/5
Weight/height index	4/5
Triceps skin-fold thickness <5%	4/5
Hypoalbuminemia <3.5 mg/dL	2/5

Hypophosphatemia was accompanied by a decreased concentration of visceral proteins (albumin) in only two of six occurrences. No obvious clinical complications of hypophosphatemia were observed in nine patients, and our review did not suggest signs or unexplained symptoms that might be due to phosphorus depletion.

COMMENT

Hypophosphatemia is a known but infrequently reported complication of nutritional rehabilitation. Our data suggested that hypophosphatemia may occur more frequently in malnourished children during nutritional rehabilitation than previously appreciated and that there is a general unawareness of this problem. Indeed, 36 of 45 malnourished patients in our study were not assessed for hypophosphatemia. The clinical importance of hypophosphatemia in our patients is unknown because timely institution of replacement therapy prevents symptoms; however, significant side effects of hypophosphatemia have been previously reported, and usually after 48 to 72 hours.¹²⁻¹⁸ Symptomatic hypophosphatemia often occurs with serum phosphorus concentrations of less than 0.32 mmol/L, affecting the hematologic, musculoskeletal, and central nervous systems.

In animals, hypophosphatemia causes decreased leukocyte adenosine triphosphate concentrations, thus depressing chemotaxis, phagocytosis, and bacterial killing, and resulting in an increased incidence of infection.¹⁹ Severe hypophosphatemia blocks red blood cell glycolysis by inhibiting the glyceraldehyde-3-phosphatase dehydrogenase reaction,¹⁸ producing a decrease in adenosine triphosphate production. Decreased adenosine triphosphate production causes a hemolytic

anemia that resolves following phosphorus repletion.¹⁴ Hypophosphatemia also impedes oxygen delivery to peripheral tissues by decreasing the production of 2-3-diphosphoglycerate, thereby increasing the affinity of hemoglobin for oxygen. Finally, platelet dysfunction with low serum phosphorus concentrations has been reported,¹⁵ including reduced adenosine triphosphate-dependent clot retraction.

Rhabdomyolysis has been observed in severe hypophosphatemia. Elevation of creatinine phosphokinase concentrations and myoglobinuria accompany acute renal failure.¹⁶ This tends to be self-limiting as phosphorus is released with the lysis of muscle cells.

Central nervous system dysfunction may be manifest by symptoms compatible with a metabolic encephalopathy, including irritability, apprehension, muscular weakness, paresthesia, dysarthric obtundation, seizures, and even coma.¹⁷ Other disturbances associated with severe hypophosphatemia include reversible cardiomyopathy, glucose intolerance, and nonspecific gastrointestinal complaints, such as anorexia, nausea, and vomiting.¹⁷

The anthropometric measurement of arm circumference and arm muscle circumference were the most predictive measures in our series of patients at risk for hypophosphatemia. In all six episodes of hypophosphatemia these were less than 5%. Laboratory measurements of visceral proteins were abnormal in only two of six episodes, namely, a low serum albumin level, which may reflect the body's ability to selectively break down less essential protein stores. All patients developing hypophosphatemia with renourishment did so within 72 hours, and most within 24 to 48 hours.

All patients who became hypophosphatemic were treated with supplemental phosphorus. Patients with minimal to moderate hypophosphatemia (concentrations higher than 0.32 mmol/L but lower than 0.97 mmol/L) were treated orally, with doses between 25 and 50 mg/kg each day (1.4 to 2.8 mEq/kg each day or 0.8 to 1.6 mmol/kg each day) of phosphorus divided four times daily. Treatment of profound hypophosphatemia (concentrations less than 0.32 mmol/L) was generally accom-

plished intravenously. Guidelines for intravenous supplementation have been published previously.¹⁸ Parenteral phosphorus should be initiated at a dose of 0.08 mmol/kg in short-term and uncomplicated cases, and 0.16 mmol/kg in a prolonged case with multiple causes (at pH 7.4, 3.1 mg/dL of phosphorus, 1 mmol/L or 1.8 mEq/L).

Professional Opportunities

FLORIDA — Seeking board-certified/board-eligible pediatrician to join busy solo pediatric practice on sunny west coast of Florida. Salaried position for one year leading to partnership. Please contact: D. French, MD, 1305-F South Fort Harrison, Clearwater, FL 34616. (813) 446-1161.

BOARD-CERTIFIED/-ELIGIBLE PEDIATRICIAN to join our 25-physician, multi-specialty group practice. All practice costs paid, full range of benefits and early partnership status. Experience our family-oriented community with its unsurpassed scenic beauty and outdoor recreational opportunities, situated midpoint between metropolitan Seattle and Vancouver, British Columbia. Contact: Shane Spray, 1400 East Kincaid Street, Mount Vernon, WA 98273. (206) 428-2524.

MASSACHUSETTS — Pediatrician, BC/BE, needed to join two others in busy private practice one hour west of Boston. Good coverage, hospital and salary. Mail CV to: Felix Perriello, MD, 114 Water Street, Milford, MA 01757. (508) 473-0231.

CALIFORNIA — PEDIATRIC INTENSIVIST to join progressive 13-bed PICU at Huntington Memorial Hospital in Pasadena, California, a major affiliate of the University of Southern California. Excellent salary, bonus and partnership opportunities. Persons with pulmonary training are encouraged to inquire. Inquiries to: Edgardo L. Arcinue, MD, Director, PICU, Huntington Memorial Hospital, 100 Congress Street, Pasadena, CA 91105. (818) 397-8688.

PEDIATRICIAN: BEMIDJI CLINIC MERITCARE is seeking a second BC/BE pediatrician to join an expanding 25-physician multi-specialty group. The local Level II hospital has 800+ deliveries per year and is affiliated with a tertiary care center with a NACHRI designated children's hospital. The area offers a wide range of recreational opportunities. Guaranteed first year salary with rewarding long term compensatory arrangements. Respond to: Robert C. Montgomery, MD, Physician Recruitment Chairman, Fargo Clinic MeritCare, 737 Broadway, Fargo, ND 58102. (800) 437-4010.

LINCOLN, NEBRASKA — BC/BE pediatrician to join three other pediatricians in a busy multi-specialty group. Available immediately, take over existing practice of retiring doctor. City of 150,000 has good schools and safe family environment. Good opportunity for professional growth. Competitive salary and benefits. Send CV to: R.Z. Gallion, P.O. Box 81009, Lincoln, NE 68501.

THREE PEDIATRICIANS SEEKING FOURTH for growing practice in 61-physician multi-specialty group in city of 10,000, 40 miles south of Madison. Attractive salary and benefits. Contact: James Raettig, MD, The Monroe Clinic, Monroe, WI 53566. (608) 328-7214.

PEDIATRICIAN will be welcomed to Oswego, New York, a 60,000 population primary service area. A college town located on Lake Ontario, 40 miles north of Syracuse. Exceptional educational, cultural and recreational activities, including salmon fishing. Contact: Garo Taft, MD, 110 West Sixth Street, Oswego, NY 13126. (315) 349-5526.

SOUTHERN CALIFORNIA—PEDIATRICIAN. A board-certified pediatrician, practicing in the San Fernando Valley for the past 10 years, is now seeking an associate. This is one of the busiest practices in the area. For further information send CV to: Manager, Professional Relations, Department ADC-9B, P.O. Box 1438, Louisville, KY 40201-1438. Or call toll-free: (800) 626-1590.

Professional Opportunities

PEDIATRICIAN — VIRGINIA. Modern 153-bed, acute care hospital has an excellent opportunity for a board-certified/-eligible pediatrician. Medical service area population of 55,000. New office building available. Very competitive financial package and relocation. Beautiful mountainous plateau area 50 miles from Roanoke, with exceptional cultural, educational and recreational opportunities. Contact: Assistant Administrator, P.O. Box 759, Pulaski, VA 24301. (703) 980-6822.

WASHINGTON — BC/BE pediatrician to join one pediatrician in busy general pediatric practice at multi-specialty clinic; excellent facilities at both clinic and hospital. Excellent salary and benefits. Prime outdoor recreational area. Contact: Terry Coplin, 840 Hill Avenue, Moses Lake, WA 98801.

UTAH — PEDIATRICIAN. An extremely busy and well-established pediatrician in Layton, Utah is now seeking an associate. This physician has two offices, one of which is located next to our 110-bed hospital. Layton, located just 20 miles north of Salt Lake City and 15 miles south of Ogden, has a service area of 140,000, 70% of whom are under the age of 35 with large families. For further information, send your CV to: Manager, Professional Relations, Humana Inc., Department ADC-9A, 500 West Main Street, Louisville, KY 40201-1438. Or call toll-free: (800) 626-1590.

WANTED!! PEDIATRICIAN

For private practice small group practice opportunities.

■ JCAH accredited community hospital in beautiful Sacramento, California seeks BE/BC pediatrician to fill a number of practice opportunities.

■ Extremely attractive assistance and relocation package available including: malpractice coverage, marketing assistance, moving expenses and a one-time recruitment bonus.

■ The Sacramento area is one of America's fastest growing communities. The income potential for pediatrician physicians is OUTSTANDING!

(916) 486-2261

Ochsner Clinic, one of the country's premier multi-specialty clinics, is seeking to hire two board-eligible/-certified

PEDIATRICIANS

to assist with coverage of the pediatric floor and the pediatric intensive care unit of Ochsner Foundation Hospital. These two house-based pediatricians (HBPs) will provide in-house coverage in conjunction with existing residents and attending staff physicians.

Ochsner Clinic, a 250+ member, multi-specialty group practice, and Ochsner Foundation Hospital, a 532-bed tertiary care facility, serve not only the New Orleans metropolitan area where they are located, but serve as a major referral center for the entire Gulf South region. The Hospital offers both neonatal and pediatric ICUs, air and ground transportation systems, a comprehensive pediatric center, an ECMO program and a special program for high risk pregnancies. The clinic's staff includes pediatric specialists in cardiology, surgery, neurosurgery, allergy, psychiatry, hematology-oncology, and other specialties, and operates a Child Development Center as well.

The compensation is competitive for similar salaried positions: \$60,000 annual salary; health insurance; life insurance; three weeks of paid vacation/education leave; and malpractice coverage.

Interested persons should forward their CV or inquiry to:

Jay P. Goldsmith, MD, Chairman

DEPARTMENT OF PEDIATRICS, OCHSNER CLINIC

1514 Jefferson Highway, New Orleans, LA 70121 • (504) 838-3900

ST. LOUIS UNIVERSITY

PEDIATRIC PULMONOLOGIST

Board-eligible or board-certified in both pediatrics and pulmonology. Responsibilities include teaching, patient care, research and directing pulmonology program.

Proficiency in invasive and non-invasive pulmonary and critical care procedures required. Send inquiries and curriculum vitae to:

THOMAS ACETO, JR., MD, CHAIRMAN

TEXAS — PEDIATRICIAN. A pediatrician is needed to establish practice in conjunction with the recruitment of a neonatologist, in College Station, Texas, the home of Texas A&M University. Financial assistance with possible future group association. Send your CV to: Professional Relations, Department ADC-9C, P.O. Box 1438, Louisville, KY 40201-1438.

NEONATOLOGIST — The Department of Pediatrics, William Beaumont Hospital is seeking a fifth full-time, academically-oriented neonatologist to join our Division of Newborn Medicine. The position involves clinical care, teaching and research. We are interested in recruiting somebody with demonstrated capability and interest in clinical and/or basic research, as well as proficiency in teaching residents. Interested individuals should submit their CV to: Daniel Batton, MD, Chief, Division of Newborn Medicine; or M. Jeffrey Maisels, MD, Chairman, Department of Pediatrics, William Beaumont Hospital, 3601 West Thirteen Mile Road, Royal Oak, MI 48072.

HOUSE BASED PEDIATRICIANS (HBPs)

Huntington Memorial Hospital of Pasadena, California, a major affiliate of the University of Southern California School of Medicine, is seeking to hire four board eligible/certified pediatricians to cover its 34-bed pediatric floor. These four house-based pediatricians (HBPs) will provide in-house coverage that traditionally would have been provided by pediatric interns or residents.

Founded in 1892, Huntington Memorial Hospital is a 606-bed non-profit medical center that serves the communities of the San Gabriel Valley of Los Angeles County. The total service area population of the San Gabriel Valley is approximately two million people. The Hospital offers a tertiary Infertility Center, Perinatal High-Risk Unit, a Neonatal ICU and renowned ECMO Center, a comprehensive Pediatric Center and a Pediatric ICU.

The compensation is competitive with the HMOs or other salaried positions in the area: \$70,000 annual salary; health insurance (medical, dental, vision); life insurance (\$50,000 term life); accidental death & dismemberment (\$50,000); paid 3-week vacation; and a \$1000 annual CME fund.

Those interested should send their CV and inquiries to:

Edgardo L. Arcinue, MD

Head, Department of Pediatrics

100 Congress Street, Pasadena, CA 91105

(818) 397-8688

MOUNTAIN STATES COMMUNITIES need pediatricians. Smaller communities with excellent incentive packages and referral bases. All close to mountain recreation. Call Rita Longino at (505) 262-1871; or send CV to: Excel of Albuquerque, 1717 Louisiana NE, Suite 218, Albuquerque, NM 87110.

FLORIDA EAST COAST — PEDIATRICIAN. An outstanding opportunity for a BC/BE pediatrician to join one of two well-established and very busy pediatric groups located along the east coast of Florida. Attractive financial package with early partnership is offered. For further information send your CV to: John Hollander, Professional Relations, Humana Inc., Department ADC-9D, 500 West Main Street, Louisville, KY 40201-1438. Or call toll-free: (800) 626-1590.

NEW YORK, NEONATOLOGIST—Department of pediatrics, State University of New York at Buffalo/Children's Hospital is seeking faculty member to join eight-member division of neonatology. Assistant or associate professor level. BC in pediatrics, BC/BE in neonatology. Division conducts NIH-sponsored laboratory research on perinatal pulmonary and circulatory physiology and clinical research in pulmonary physiology, immunology and gastroenterology, including five years experience with surfactant therapy. CV to: Frederick C. Monn, MD, Chief, Division of Neonatology, Children's Hospital, 219 Bryant Street, Buffalo, NY 14222. Affirmative action/equal opportunity employers.

THE DEPARTMENT OF PEDIATRICS at William Beaumont Hospital is seeking a qualified pediatrician for the position of Director, Division of Pediatric Infectious Disease. William Beaumont Hospital is a 934-bed general hospital located thirteen miles north of Detroit in Royal Oak, Michigan. We have 60 general pediatric beds, a 30-bed NICU and 6,000 deliveries annually. Our department has a staff of 120 pediatricians and 20 full-time pediatric subspecialists. There are some 4,000 admissions annually to our general pediatric floor and 20,000 pediatric visits to the emergency center and outpatient clinics. We are a teaching hospital with independent residency programs in pediatrics and medicine-pediatrics, affiliated with the University of Michigan and Wayne State University. Interested candidates should call or submit their curriculum vitae to: M. Jeffrey Maisels, MD, Chairman, Department of Pediatrics, William Beaumont Hospital, 3601 West Thirteen Mile Road, Royal Oak, MI 48072. (313) 551-0412.

COLORADO — BC/BE pediatrician to join well-established, two-person practice. Active Level II nursery. Reply to: Richard Booth, MD, 1148 East Elizabeth, Fort Collins, CO 80524. (303) 484-4871.

The Doctor Is In... ...private practice in the perfect community.

If that's your goal, Humana can help. We have over 80 hospitals in 20 states. Chances are we know of a private practice opportunity in the location of your choice. Consider these communities:

- **Russellville, Alabama**
- **Anchorage, Alaska**
- **Los Angeles County, California**
- **Florida East Coast**
- **Atlanta, Georgia**
- **Lexington, Kentucky**
- **Louisville, Kentucky**
- **Somerset, Kentucky**
- **Chattanooga, Tennessee**
- **Lebanon, Tennessee**
- **Abilene, Texas**
- **College Station, Texas**
- **Layton, Utah**
(Salt Lake City/Ogden)

We have other Pediatric opportunities not listed here.

For further information, call TOLL-FREE 1-800/626-1590, or send your curriculum vitae to: Manager, Professional Relations, Humana Inc., Dept. ADC-9, 500 West Main Street, Louisville, KY 40201-1438.

September 26-October 1, 1989 Chicago Spring and Fall 1990 — Sites to be Chosen

Now, your review and update for board exams and practice

Sponsored by the Osler Institute

OBJECTIVES:

- Improve basic and clinical knowledge in pediatrics
- Assist residents and fellows in organizing study
- Prepare candidates to take examinations
- Provide practicing pediatricians with a review and update

METHODS:

- HOME STUDY MATERIALS consisting of a syllabus of questions with assignments and answers
- SEMINAR with projection slides and syllabus
- PRACTICE EXAMS with oral and written parts

The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well. **

"Accommodations were comfortable..." *

GOALS AND LOCATION: The course is held the week before oral and written board exams. Sites are chosen for excellent study and minimal cost of hotel and travel for board candidates. Your best value is to repeat the seminar for half price the week before your written or oral exam. The course will be held at the Holiday Inn Willowbrook, 7800 Kingery Highway, Willowbrook — 15 miles south of O'Hare and 10 miles west of Midway Airport. Rates are \$65 single and \$88 double.

"...and those little extras..." *

LOWEST AIR FARES: Reliable Travel offers you the lowest air fare — often below super-saver rates. Please call toll-free 1-800-548-8185 and identify yourself with this Osler course for special group fares.

"...remarkably complete and pleasant..." *

PLACEMENT SERVICE: For a practice opportunity write or call 1-800-356-7537.

"...the most education for the money..." *

FEES AND COURSE HOURS:

- **Course Hours:** 60 hrs.
- **Practicing Pediatrician:** \$660
- **Residents and Fellows:** \$440
- **Repeating course within 3 yrs.:** half price
- **Add 10% within 10 days of course.**
- **Fees do not include lodging or meals.**
- **Attendees not in course hotel add \$8/day.**
- **Deposit of \$50 will reserve your position.**
- **Most home study material will be mailed after half the registration fee is received.**

"...home study material was extremely helpful..." *

REFUNDS: Subject to a \$50 fee, refunds will be made until the seminar begins.

- Cancellation after mailing home study material requires retention of half the fee.

"I feel [the course] helped me pass the boards..." *

RICHARD W. GAST
PRESIDENT

... on the consumer promotion of infant formula.

There is a development that undermines your control over the infant's diet and health, and that undermines breastfeeding—the advertisement of formulas directly to the mother through TV, magazines and mail.

On June 1, the President of the American Academy of Pediatrics sent a letter to all Fellows of the Academy reaffirming its stance against consumer advertising, and expressing concern that other formula companies might follow Nestlé/Carnation.

This concern was justified. On June 15, it was announced at a press conference that Mead Johnson/Bristol-Myers will be producing an infant formula to be sold and marketed under the Gerber label. Part of the program is a multimillion-dollar budget for advertising the formula directly to mothers via TV and print.

Speaking at the press conference, Gerber Products Division President Robert L. Johnston, Jr., said that Gerber was entering the market because it had, "identified significant changes in usage that convinced us the timing was right. . . ."

"First," he said, "there is a rapid decline in breast-feeding after mothers leave the hospital." And, "... parent decision regarding baby formula brand selection has grown. . . ."

The irony is inescapable and appalling. In other words, because breastfeeding is declining, more infant formulas should be promoted to the mother. In other words, because some mothers are making feeding decisions on their own, even more mothers should follow suit.

When Nestlé/Carnation entered the marketplace and, again, when Mead Johnson/Bristol-Myers joined with Gerber, we reexamined the Ross philosophy of promoting SIMILAC® Infant Formulas. The result of our deliberations was an even deeper resolve to support the doctor/patient relationship.

Our philosophy remains unchanged. Ross Laboratories has no plans to resort to direct consumer advertising for SIMILAC and our other infant formula products.

We will continue as an ally of health care professionals by supporting your prerogative to prescribe and recommend products as training and experience dictate.

We stand behind you.

Richard W. Gast

AJDC, American Journal of Diseases of Children (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the American Medical Association. Second-class postage paid at Chicago and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the American Journal of Diseases of Children are as follows: \$48 for one year, \$81 for two years in the United States and US Possessions; all other countries, \$58; two years, \$101 for surface delivery. (For expedited air delivery to most countries, a surcharge for one year subscription, \$30 for two years.) Rates for subscriptions for delivery to Korea are available through exclusive agents—contact the publisher. **Special rates for medical students in the United States and US Possessions are available.** Address: American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312) 280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes for AJDC, American Journal of Diseases of Children. Attention: Subscription Department, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new mailing label, and your new zip code.

ADVERTISING OFFICES: Eastern: 600 Third Ave, Suite 3700, New York, NY 10016 (Marjorie Corcoran [212-867-6640]; Representative: Phillip B. Altamore); Midwest/Farwest: 535 N Dearborn St, Chicago, IL 60610 (Manager: Thomas J. Carroll [312-280-7182]; Representative: Michael J. Farwest)

Advertising Principles: Each advertisement in this issue has been reviewed and accepted in accordance with the principles governing advertising in AMA scientific publications. A copy of these principles is available upon request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

They trust you to recommend what's best for them.

LIQUIPRIN has earned the confidence of parents and pediatricians with dependable relief of fever and pain for over 25 years.

The LIQUIPRIN acetaminophen formula does not contain aspirin or alcohol and has a pleasant-tasting fruit flavor that babies like.

The LIQUIPRIN advanced dropper system has a larger tube and bulb, making each dose easier to measure. The bottle is unbreakable plastic with a safety-sealed, child-proof cap. And LIQUIPRIN is priced well below Tylenol®.

LIQUIPRIN. Pediatricians recommend it over 1½ million times a year. For good reason.

Available as an Elixir, too.

Tom Smith, MD

PEDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus var. capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus var. capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combing of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: Teratogenic Effects: Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp (especially behind the ears and on nape of the neck). Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combing of nits is not required for therapeutic efficacy, but may be done for cosmetic reasons or to meet school "no nit" policies. A nit comb is provided.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz. weighing 56 g. (NDC-0081-0780-81)

Store at 15°-25°C (59°-77°F).

wall membrane.

HAEMOPHILUS b DISEASE.

3. Opsonic activity:
ProHIBiT® induced antibody stimulates circulating leukocytes to phagocytize bacteria.

DEFENDS

ProHIBiT® defends against Haemophilus b disease in three important ways:

1

PRIMES

THE IMMUNE SYSTEM

ProHIBiT® primes the immune system to produce memory cells that stimulate rapid production of antibodies when challenged^{1,2} with native polysaccharide.

2

PROMOTES

BACTERICIDAL ACTION

ProHIBiT® promotes bactericidal action² of the immune system to help your patients fight off infection.

3

ENHANCES

PHAGOCYTOSIS

ProHIBiT® induced antibody enhances phagocytosis² (opsonic activity).

If you wish to order ProHIBiT®, call the following toll-free number: 1-800-VACCINE (1-800-822-2463).

Connaught Laboratories, Inc.

ProHIBiT®

**Haemophilus b Conjugate Vaccine
(Diphtheria Toxoid-Conjugate)**

**PROVEN SAFE AND WELL TOLERATED
AFTER MILLIONS OF IMMUNIZATIONS¹**

Please see brief summary of prescribing information on last page of this advertisement.[†]
[†]ProHIBiT® is currently indicated for children 18-60 months of age.

[†]Serious adverse experiences (seizures, Guillain-Barré syndrome), have been rarely reported in association with ProHIBiT® immunization.

Haemophilus b Conjugate Vaccine (Diphtheria Toxoid-Conjugate)

Caution: Federal (U.S.A.) law prohibits dispensing without prescription.

BRIEF SUMMARY

INDICATIONS AND USAGE

ProHIBiT is indicated for the routine immunization of children 18 months to 5 years of age against invasive diseases caused by *Haemophilus influenzae* type b. As with other vaccines, several days following administration of ProHIBiT are required for protective levels of antibody to be attained.

A booster dose of ProHIBiT is *not* required.

ProHIBiT will not protect against *Haemophilus influenzae* other than type b or other microorganisms that cause meningitis or septic disease.

No impairment of the immune response to the individual antigens was demonstrated when ProHIBiT and Diphtheria and Tetanus Toxoids and Pertussis Vaccine Adsorbed (DTP) were given at the same time at separate sites.

Because the safety and efficacy of ProHIBiT have not been established in children less than 18 months of age, ProHIBiT is not indicated for use in this age group at this time. Studies to establish the safety and efficacy of ProHIBiT in children less than 18 months of age are ongoing.

ProHIBiT IS NOT RECOMMENDED FOR USE IN CHILDREN YOUNGER THAN 18 MONTHS OF AGE.

CONTRAINDICATIONS

HYPERSENSITIVITY TO ANY COMPONENT OF THE VACCINE, INCLUDING THIMEROSAL AND DIPHTHERIA TOXOID, IS A CONTRAINDICATION TO USE OF THIS VACCINE.

WARNINGS

If ProHIBiT is used in persons with malignancies or those receiving immunosuppressive therapy or who are otherwise immunocompromised, the expected immune response may not be obtained.

As with any vaccine, ProHIBiT may not protect 100% of individuals receiving the vaccine.

PRECAUTIONS

GENERAL

As with the injection of any biological material, Epinephrine Injection (1:1000) should be available for immediate use should an anaphylactic or other allergic reaction occur.

Prior to an injection of any vaccine, all known precautions should be taken to prevent adverse reactions. This includes a review of the patient's history with respect to possible hypersensitivity to the vaccine or similar vaccines.

Any febrile illness or acute infection is reason to delay the use of ProHIBiT.

As reported with *Haemophilus b* polysaccharide vaccine, cases of *Haemophilus b* disease may occur in the week after vaccination, prior to the onset of the protective effects of the vaccine.

Special care should be taken to ensure that the injection does not enter a blood vessel.

A separate, sterile syringe and needle or a sterile disposable unit should be used for each individual patient to prevent transmission of hepatitis or other infectious agents from one person to another.

ALTHOUGH SOME IMMUNE RESPONSE TO THE DIPHTHERIA TOXOID COMPONENT MAY OCCUR, IMMUNIZATION WITH ProHIBiT DOES NOT SUBSTITUTE FOR ROUTINE DIPHTHERIA IMMUNIZATION.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY

ProHIBiT has not been evaluated for its carcinogenic, mutagenic potential or impairment of fertility.

PREGNANCY

REPRODUCTIVE STUDIES — PREGNANCY CATEGORY C

Animal reproduction studies have not been conducted with ProHIBiT. It is also not known whether ProHIBiT can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. ProHIBiT is NOT recommended for use in a pregnant woman.

ADVERSE REACTIONS

When ProHIBiT alone was given to over 1,000 adults and children, no serious adverse reactions were observed. Thrombocytopenia was seen in one adult but a causative relationship was not established.

When ProHIBiT was given with DTP and Inactivated Poliovirus Vaccine to 30,000 young infants, the rate and extent of serious adverse reactions were not different from those seen when DTP was administered alone. Allergic reactions such as urticaria were infrequently observed.

Selected adverse reactions following vaccination with ProHIBiT (without DTP) in subjects 16-24 months of age are summarized in Table.

TABLE
Percentage of Subjects 16-24 Months of Age Developing
Local Reactions or Fever to One Dose of
Haemophilus b Conjugate Vaccine (Diphtheria Toxoid-Conjugate)

	No. of Subjects*	Reaction %		
		6 Hours	24 Hours	48 Hours
Fever >38.3°C	281	1.1	2.1	1.8
Erythema	285	—	2.5	0.4
Induration	285	—	1.0	0.4
Tenderness	285	—	4.6	0.7

*Not all subjects had measurements at all time periods.

Other adverse reactions temporally associated with administration of ProHIBiT included diarrhea, vomiting, and crying and occurred at a frequency of ≤1.2%.

Adverse reactions in clinical evaluations among 689 children, 7-14 months of age, 24 hours after receiving a single dose of ProHIBiT, were observed and compared to 139 children who received a saline placebo. There were no significant differences in the reaction rates for fever, erythema, induration, and tenderness between the two groups.

DOSAGE AND ADMINISTRATION

Parenteral drug products should be inspected visually for extraneous particulate matter and/or discoloration prior to administration whenever solution and container permit. If these conditions exist, vaccine should not be administered.

ProHIBiT is indicated for children 18 months to 5 years of age. The immunizing dose is a single injection of 0.5 ml given intramuscularly in the outer aspect area of the vastus lateralis (mid-thigh) or deltoid.

Each 0.5 ml dose contains 25 mcg of purified capsular polysaccharide and 18 mcg of conjugated diphtheria toxoid protein.

Before injection, the skin over the site to be injected should be cleansed with a suitable germicide. After insertion of the needle, aspirate to ensure that the needle has not entered a blood vessel.

DO NOT INJECT INTRAVENOUSLY.

HOW SUPPLIED

Vial, 1 Dose (5 per package) — Product No. 49281-541-01
Vial, 5 Dose — Product No. 49281-541-05
Vial, 10 Dose — Product No. 49281-541-10

STORAGE

Store between 2°-8°C (35°-46°F). DO NOT FREEZE.

This department of AJDC is reserved for comment, criticism, observation, and discussion of "issues of current concern and importance for children's health." The Editor encourages our readers to express themselves on a variety of topics and issues. Further, we encourage the submission of unique and brief clinical and scientific observations that do not fulfill the criteria for original articles.

Resident Stress

Sir—Hoekelman¹ recently identified factors that lead to stress during residency training. He claimed that causes of stress go beyond long work hours and the severely ill population for whom residents care, and stated that the stress to which residents are exposed is accentuated by the uncertainty of their futures once training is completed.

Hoekelman suggested many changes that residency programs can adopt to reduce the stressors that are inherent in the present system. However, significant changes in residency training will not be implemented until members of the medical faculty begin to understand the transformations that have begun to take place in the provision of health care. These have occurred as a result of the corporate restructuring of health care systems. Since the rise of what Relman² terms the *medical-industrial complex*, hospitals are often managed by business executives rather than the traditional physician administrator who once managed residency training and hospital services. In light of the changes in the management of hospital systems, faculty need to be advocates for the physical and educational needs of the house staff. This would enable residency training programs to meet the changing needs of the health care organization.

In today's medical marketplace, the expertise offered by the business community is necessary to maintain the viability of health care facilities. However, profitability factors may not translate into the most educationally sound residency experience where a balance exists between service and education. Tension between a resident's service commitment and educational pursuits may be intensified by decisions made by corporate man-

agers who are insensitive to or unaware of the demands of the residency process.

In light of these concerns, Hoekelman's suggestions for changes in the environment in which residents learn is timely and appropriate. Hoekelman's perspective finds a blueprint for an approach to the improvement of physician education described by Jonas.³ In his book, Jonas examines the US health care provision system and the process through which graduate physicians progress to emerge as "doctors." He contends that the present system, on which medical training and practice is based, fosters in itself an unhealthy approach to both work and education. Our disease-oriented health care system gives minimal support to prevention and health maintenance endeavors on the part of physicians-in-training.

In the 1980s, medical centers have emerged as sites for disease treatment and acute care intervention. Public policies and financial resources for health care are developed to cope with disease rather than to encourage health promotion and disease prevention. A nonprevention orientation is entrenched even within the physician training process, which ignores the requisites of health and stands as the model for an unhealthy living and learning environment.

Jonas³ addresses Hoekelman's concerns and proposes a preventive, health-promotion-based model for medical education entitled Health Oriented Professional Education (HOPE). HOPE includes five points that should be incorporated into the philosophy and curriculum of medical schools and residency programs. The proposal encourages (1) a prevention-based orientation for a program that emphasizes outpatient care focused on health maintenance and preventive

screening; (2) faculty attitudes that foster student/resident health, including reasonable expectations for resident responsibilities and encouraging postcall residents to complete their work early and go home to sleep; (3) expressed emphasis on active learning, utilizing a problem-based mode of teaching to provide feedback and build self-esteem; (4) increased use of ancillary services and the incorporation of computer technology to simplify menial tasks and enable the resident to reduce his or her secretarial responsibilities; and (5) encouraging physician-teachers to seek formal training in the educational process to enhance the quality of medical education.

The Jonas³ model provides one approach to the reduction of resident stress. Other approaches exist as well. The common theme among various approaches is that residency training must incorporate principles of healthy living while meeting the service requirements and educational objectives of the programs.

As Hoekelman stated, pediatric and other medical educators are largely responsible for the ill effects of the residency training programs on practitioners. The improvement of residency training depends on the commitment of the faculty to engage corporate administration in the needs of the residents and to serve as sentinels for the residents during this process. Residency training should occur in an environment that provides patient care while ensuring healthy personal and professional development among the participants.

Stress During Residency Training

Sir:—We read with interest the article by Hoekelman regarding stress experienced during pediatric residency training in the February 1989 issue of *AJDC*.¹ This article adequately outlined the problem of resident stress and proposed some very useful solutions.

I think we can all recall similar discussions and proposed solutions dating back at least 15 years. Very little has changed, presumably because it has not served the interest of hospitals to follow through on these and other means of resolving the issue of stress during residency training. In New York State in particular, we have been presented with recommendations by the State Department of Health regarding limitations on working hours, the use of nonphysician personnel for responsibilities such as blood drawing and starting of intravenous lines, and the use of computers to facilitate retrieval of laboratory results. Very few programs are even attempting to comply with these regulations by the July 1989 deadline, again illustrating the difference between what hospitals say they want for residents and what they are willing to provide.

With regard to Hoekelman's proposals, I wonder how effective restricting the maximum shift to 29 hours would be in reducing fatigue and stress, particularly if this schedule is followed on an every third night basis. We feel that if one truly wishes to reduce resident fatigue it is insufficient to reduce the maximum shift simply from 34 to 29 hours. Doing away with moonlighting is a method of uncovering another potential source of resident stress, that is, financial stress. Many of our first-year residents have debts related to undergraduate and medical education that are in excess of \$30 000. These residents also have families. To expect them to repay these debts and manage a family on the usual house staff salary puts additional pressure on a house officer. The issues of ancillary personnel and computerization are not addressed by Hoekelman, yet there is certainly no greater waste of a resident's time than to wait on the telephone until a technician can re-

cover a laboratory result or to spend hours performing technical procedures long after he or she has been credentialed in these same procedures.

In our pediatric residency program, we have adopted a maximum 16-hour shift in inpatient ward areas and will have maximum 24-hour shifts on an every fourth night basis in intensive care areas by July 1989. Postgraduate level 1 residents have at least one 24-hour period of relief from direct patient care activities each week. Work schedules average 80 hours or less for each 4-week module. Moonlighting is allowed as long as the maximum shift does not exceed 24 hours and the maximum hours worked per week does not exceed the 80-hour limit. We have moved ahead with educating nurses and other nonmedical personnel in the starting of intravenous lines and drawing of blood. While there are imperfections in the system (which we hope to resolve), it is clear that the level of fatigue and emotional stress among our current postgraduate level 1 residents is substantially less than in past years. We hope to have available a more formal evaluation of our experiences with these modifications in the near future. The purpose of this commentary is to reassure those institutions that wish to move forward with similar revisions that house officers can benefit from such changes if the programs are willing to make them.

Strategies to Prevent Household Electrical Injuries in Children

Sir:—The article by Baker and Chiaviello¹ in the January issue of *AJDC* is an important addition to the scanty literature on children's electrical injuries and strategies to prevent them. The American Academy of Pediatrics' *Guidelines for Health Supervision*² and five of seven widely used pediatric textbooks that we reviewed suggested the use of outlet plugs as a strategy to prevent these injuries.³⁻⁹ None of these references detailed the various types of outlet plugs available

or their potential limitations and dangers. Baker and Chiaviello described some of their limitations, but we believe that there are other important considerations and potential problems with them that deserve description.

As Baker and Chiaviello noted, "infant toys should not simulate common household items. . . ." Similarly, we believe that safety items should not simulate toys, especially if they themselves are potentially harmful to children. This, unfortunately, is the case with many outlet plugs. Some are actually embossed with attractive designs, such as bears (a common transitional object for children), thereby enticing children to remove them from outlets. Many of these devices are also small enough to pose the danger of aspiration to children.

The Consumer Product Safety Commission and American Academy of Pediatrics collaboratively created the commercially available No Choke Testing Tube (Fig 1). This practical device serves as the gauge for the current federal small parts and toy safety regulations regarding the minimum size allowed for any object intended for use by children under the age of 3 years. Nine of 10 outlet plugs purchased at Boston, Mass, supermarkets, hardware stores, and toy stores were small enough to fit into the No Choking Test Tube, and thus failed the test. In addition, any safety device that requires behavior change has reduced protective value when compared with devices that automatically offer protection. Most outlet plugs currently available must be removed whenever the outlet is used and then put back into the outlet. It is likely then that they will be used only sporadically. This may increase the risk to toddlers if parents, unaware of their potential danger, leave the plugs lying about.

As part of Boston's Childhood Injury Prevention Program, pediatricians at selected health centers and hospital-based clinics, day-care providers, and public health nurses have distributed outlet plugs to families for the past 3 years. A number of health care providers and parents have observed children playing with the small outlet plugs and putting them into their mouths. Furthermore, people making home visits have noted not only unprotected outlets but loose outlet plugs in families' homes.

Baker and Chiaviello's proposed outlet cover is in principle laudable. It addresses one limitation of outlet plugs; that is, the proposed outlet

Fig 1.—No Choke Testing Tube and an assortment of outlet plugs.

Fig 2.—Sanitoy outlet cover, front and rear views.

cover is permanent once installed. Any safety device that requires a three-step procedure, such as the one they propose, however, seems unlikely to be used regularly and appropriately by large numbers of individuals. We distribute an outlet cover manufactured by Sanitoy (Fitchburg, Mass) (Fig 2) that requires a one-step procedure with either a two- or three-pronged electrical plug. This cover requires only one screw and is a permanent fixture. It is extremely difficult to gain access to the outlet holes by using anything but an electrical appliance plug. The automatic release and closure prevent access to the outlet once an appliance is unplugged. In the case of double outlets, each one is

independently closed or opened depending on use. This cover is fitted over the existing outlet plate and no contact with exposed wires is necessary or possible, whereas the cover proposed by Baker and Chiaviello would require replacing the regular outlet plate.

Injury-prevention activities must be easily integrated into everyday habits and routines if they are to be widely adopted by families. We must also be cautious that we do not distribute or encourage the use of injury-prevention technology without educating parents about the technology's limitations and potential dangers.

'Mangoism'

Sir.—We recently cared for a 16½-month-old Equadorian boy who presented with orange coloration and failure to thrive.

The child presented to the clinic for routine health care. Concern was raised about the child's growth. He weighed 8.3 kg (less than the fifth percentile), showing a 28-g gain in 11 weeks. His height was 76 cm (10th percentile) and his head circumference was 46.5 cm (10th percentile). The family indicated that this child had become difficult to feed and denied any specific food preferences.

The physical examination was remarkable for a very slight toddler whose skin was an intense orange color that was most obvious on his palms and soles. There was no scleral icterus. The remainder of the examination was unremarkable. Because of concern about this child's poor weight gain and unusual coloration, he was admitted to the hospital.

At the time of admission, the patient's hemoglobin level was 127 g/L, his hematocrit value was 0.39, and his white blood cell count was $9.8 \times 10^9/L$, with a differential cell count of 0.35 polymorphonuclear cells, 0.63 lymphocytes, and 0.02 monocytes. The urinalysis showed a pH value of 5; the results of the glucose, ketones, and protein tests were negative. The urine culture yielded no growth. The serum glucose level was 4.8 mmol/L. The total bilirubin value was 5.13 $\mu\text{mol/L}$, thyroxine level was 102 nmol/L, triiodothyronine uptake was 0.38, and thyroid-stimulating hormone was 4.0 mU/L. Electrolyte levels and chemistry profiles were within normal limits.

A diet history eventually obtained from the mother and family indicated that this child was fed approximately 16 ounces daily of whole milk, cereals,

commercially prepared pureed or strained meats, soups, and sweet fruits, especially mangoes. The mangoes were the only food he regularly ate well, generally consuming about 8 oz daily in the form of commercial baby food over the previous 2 months.

In the hospital, the boy was found to be a difficult eater with significant acting-out patterns at meal times. Over time, the child learned to self-feed with his fingers and to accept a more balanced assortment of food-stuffs. With the omission of mangoes from his diet, the orange color faded within 2 weeks. The child began to gain weight. The family did not accept a behaviorally based cause of his failure to thrive and signed the toddler out of the hospital against medical advice.

We conclude that the skin coloration was due to carotenemia and that both the carotenemia and the failure to thrive occurred as a result of overeating a low-calorie, carotene-rich fruit, the mango.

Carotenemia can be associated with a multitude of clinical disorders or with overzealous consumption of carotene-rich plant foods.¹ Reported cases of dietary carotenemia have mainly discussed the overconsumption of vegetables, such as pumpkin² and notably carrots.^{1,3-6} Although carotenemia is assumed to occur from the excessive consumption of carotene-rich fruits, it is rarely reported. Sharman⁴ described a Japanese woman who developed a yellow coloration from eating oranges.

Carotenemia itself is benign and the usual treatment for the symptoms is withdrawal of the carotene sources. However, we would like to stress the importance of this condition as a marker for possible abnormal dietary practices. This case stressed several points for us.

1. An immoderate intake of one food usually implies a disproportionate intake of others, especially in children.
2. The traditional association of carotenemia with carrots should be broadened to include all deeply colored fruits. Consumption of exotic fruits, such as papaya and mangoes, is increasing with the availability of intercontinental transport and the demand for them by immigrants from southern climates.
3. The physical form of the carotene may be more important than the amount in children because absorption of carotenoids apparently increases

the more a food is pulverized.⁷ Strained mangoes are potentially more carotenemic than perhaps whole fresh mangoes in an equal amount.

4. Along with possible protein-calorie malnutrition, carotenemia may be seen as another consequence of prolonged overuse of strained foods.

Choking on a 'Large' Object: Applications for Regulation and Practice

Sir.—Choking on foreign bodies is a preventable cause of morbidity and mortality in small children. In 1985, small toys or their parts were responsible for 12 000 such injuries in the United States, with 18 fatalities reported during the period from January 1985 to September 1986.¹ We describe a child who suffered near-fatal choking on an object considered "large" by current standards.

Patient Report.—A 10-month-old male infant and his 3-year-old sister were seen for well-child visits by their pediatrician, who administered the Denver Developmental Screening Test. That evening, their father found the infant thrashing about on the bed where he and his sister had been playing, his head extended and eyes rolled back. He felt a hard object in the child's mouth but was unable to remove it. The child became dusky and limp. After 2 to 3 minutes, a 2.5-cm wooden cube was dislodged. The child's mouth was bloody and he was thought to be in cardiorespiratory arrest. Cardiopulmonary resuscitation was initiated and continued for an estimated 3 minutes before the child became responsive. Twelve minutes after receiving the call, paramedics found the child to be alert and in no distress. In the emergency department, examination by an otolaryngologist revealed a 5-mm superficial tear in the right anterior tonsillar pillar without active bleeding; the child was otherwise well. The sister later stated that she had kept the

Small parts test fixture.³

block, which had come from the Denver Developmental Screening Test kit, and had later put it into her infant brother's mouth. Follow-up examination 2 weeks later showed complete healing of the pharyngeal lesion.

Comment.—The size of small toys and their parts marketed in the United States is regulated by the Federal Hazardous Substances Act. The Consumer Product Safety Commission (CPSC) has established a method for determining whether an article presents a choking hazard: the sale of toys and other articles intended for use by children under age 3 years is prohibited if they are small enough to fit entirely within a truncated cylinder with a diameter of 3.18 cm and depth ranging from 2.5 to 5.72 cm (Figure). Based on the recommendations of the American Academy of Pediatrics,² this size was thought to represent the size above which complete airway obstruction is unlikely to occur.

However, the CPSC has reported 194 choking incidents in children, including 37 deaths, caused by objects larger than the cavity in the small parts test fixture for the period from July 1973 to May 1983.³ Affected children ranged in age from 1 month to 4 years; one half were 4 to 8 months old. For the 136 objects whose size was available, 78 (57%) had diameters larger than 3.28 cm, and were implicated in 5 of the fatalities. Only 4 objects (4%) larger than 4.29 cm in diameter were involved in choking episodes, none of them fatal. At least 41 incidents (36%), including 10 fatalities were caused by objects with a diameter smaller than that of the test fixture but with length longer than the 5.72-cm depth of the test fixture. The CPSC

report concluded that "objects with diameters of 1.65 inches [4.19 cm] or less are choking children . . . it appears that the 1.25 inch [3.18-cm] dimension of the small parts tester is not adequate to prevent penetration of an object into the mouth."

The regulation has not been changed, however, and in April 1987 the Consumer Federation of America (CFA) and the New York State Attorney General petitioned the CPSC to increase the diameter of the small parts test standard.^{4,5} Based on the CPSC data, the petitioners contended that the minimum diameter permitted for toys for small children should be increased to 4.3 cm, and that the length requirement was irrelevant to preventing choking. This diameter equals the size of the infant mouth and represents the minimum size required by the current pacifier regulation.³ Such a standard would have prevented all but 5 of the 136 incidents reported by the CPSC, and all of the fatalities.

In the patient we describe, near-fatal choking was caused by a wooden block from a Denver Developmental Screening Tests kit, which measures 2.5 cm on each side and has a diameter of 3.6 cm. This is larger than the 3.18 cm diameter of the current test fixture, but smaller than the 4.3-cm diameter proposed by the Consumer Federation of America/New York State petition. Pediatricians should be aware that objects considered safe by current standards can cause potentially fatal choking in small children, including Denver Developmental Screening Test blocks from the clinic or office that find their way into homes with their young patients.

Mucocutaneous Lymph Node Syndrome: Is There a Relationship to Mercury Exposure?

Sir:—We were interested in the article by Krowchuk et al¹ in the November 1988 issue of *AJDC* about the occurrence of exanthem limited to the diaper area in a 21-month-old male child diagnosed as having Kawasaki disease. We were disappointed that the authors failed to note the type of diapers used by this child. This case brings to mind a 1981 report² of acrodynia, or "pink disease," in thousands of infants in Buenos Aires, Argentina, who were poisoned by mercury from commercially laundered diapers. The causative compound was phenylmercury, which was added to the laundering process because it is such an effective fungicide and reduces the odors produced during washing and storing. A causal relationship of Kawasaki disease and inorganic mercury poisoning was first suggested by Cheek,³ following observations that acrodynia has many symptoms similar to mucocutaneous lymph node syndrome (MLNS).

Acrodynia, or "pink disease," was traced by Warkany and Hubbard⁴ to "medicinal" use of teething powders containing calomel (mercurous chloride) and mercury-containing ointments for the treatment of impetigo. Mercurials were also widely used as antihelminthic agents. Acrodynia is characterized by hyperemic pharynx and lips, a markedly red strawberry tongue, and loss of teeth. In the peripheral extremities, symptoms include indurative edema, emaciation and erythema of the skin, and membranous desquamation with pink to red fingertips, palms, and soles. Other salient signs and symptoms include bilateral conjunctival hyperemia, polymorphous exanthem, cervical adenopathy, photophobia, arthralgia, thromboses, anorexia, and irritability. Fever and coronary artery aneurysms have not been associated with acrodynia. Naturally, not every instance shows the same profile of effects, and some symptoms, particularly during the early stages of the disease, are so nonspecific that the pediatrician may be easily misled. While the similarity

in symptoms between MLNS and acrodynia does not necessarily prove the identity of the two diseases, the clinical manifestations of MLNS, justifiably, led investigators to question the role of inorganic mercury in its origin. Although Kawasaki⁵ failed to detect elevated mercury levels in his patients' hair, reports^{6,7} of elevated urinary mercury excretion in patients with MLNS led some investigators⁶ to suggest that elevated IgE levels reflect an allergic aspect and a hypersensitivity reaction to inorganic mercury poisoning.

Mercury, a ubiquitous metal, exists in a number of physical and chemical forms. Inorganic mercury exists in the metallic form (Hg^0), in the mercurous form (Hg_2^{2+}), and in the mercuric form (Hg^{2+}). Both the mercurous and mercuric cations can form a number of inorganic compounds. In addition, the mercuric cation is able to form covalent bonds with carbon atoms to produce organic species of mercury. Biomethylation reactions in fresh and saline water carried out by methanogenic bacteria result in the formation of organic mercury, which accumulates in the aquatic biota and thereby enters the human food chain. Today, human exposure is mainly to two forms of mercury species: occupational exposure to the vapor of metallic mercury, and exposure to methylmercury (MeHg) via the food chain, primarily from fish and its products.

Having a flameless, cold-vapor atomic-absorption technique at our disposal, we further explored a possible relationship between inorganic mercury exposure and MLNS. The urine is the best indicator of long-term exposure to inhaled mercury vapor, and hair is a valuable indicator in the assessment of MeHg's body burden. When the distribution process of MeHg is completed, the concentration ratio between hair and blood remains constant and the hair concentration of the organometal is a fixed multiple of its blood concentration ($\times 250$). Thus, if measured longitudinally, hair samples can catalog a month-to-month variation in blood MeHg concentrations and a history of exposure. Other forms of mercury, because of their conversion to divalent mercury, behave in a similar fashion to inhaled mercury vapor.

Three pediatric patients admitted to Strong Memorial Hospital between October 1985 and May 1986 with a diagnosis of MLNS were examined for evidence of elevated mercury levels. The results obtained are as follows:

Patient No.	Urine, ng/mL		Hair, μ g/g
1	0.95		0.52
2	0.47		1.19
3	2.32	Not detectable	

("Normal" values for mercury in urine and hair are less than 20 ng/mL and <7.5 μ g/g, respectively. The technique has a sensitivity of approximately 0.5 ng of mercury in biological samples.)

At present the cause of Kawasaki disease remains unknown. In a small cohort of patients with MLNS, we failed to corroborate a link between MLNS and inorganic mercury exposure. No potential source of mercury exposure could be identified in these three patients, and mercury levels were not elevated. It remains conjectural whether MLNS is a common pathway for multiple pathogenic factors, possibly including inorganic mercury poisoning. While our results refute the hypothesis that, by itself exposure to inorganic mercury alone is responsible for MLNS, we must systematically continue the search for potential causative factors.

In Reply.—We appreciate the thoughtful comments of Drs Aschner and Aschner regarding the possible relationship of mercury exposure and the development of Kawasaki disease. As they note, a number of less obvious or frankly occult exposures to mercury exist, including that resulting from the use of certain diaper rinses. The patient described by us,¹ however, wore

of the Ultrapampers variety. To our knowledge, mercury is not used in the manufacture of these products, thus obviating diapers as a source of potential exposure.

Acro-dynia is appropriately included in the differential diagnosis of the cutaneous and systemic manifestations of Kawasaki disease. While Kawasaki disease and acro-dynia share certain similarities of presentation, these processes may be distinguished by their unique clinical manifestations.^{2,3} Kawasaki disease has a sudden onset and a self-limited course, with the majority of overt clinical findings resolving within 1 month. In contrast, acro-dynia manifests an insidious onset and protracted course. Fever of 5 or more days' duration, uncommon in patients with acro-dynia, is a hallmark of Kawasaki disease. Although bilateral conjunctival hyperemia may occur in both disorders, photophobia is more commonly observed in acro-dynia, affecting more than one half of all patients. Both Kawasaki disease and acro-dynia produce changes involving the extremities, including erythema, swelling, and peeling. However, while arthralgias or arthritis may occur in Kawasaki disease, a prominent manifestation of acro-dynia is severe pain of the feet and hands that may limit ambulation or cause patients to rub their hands together. The erythema associated with acro-dynia has a distinctive pink or scarlet hue (hence, the name "pink disease") that, early in the course of the disease, involves the distal portions of the nose, fingers, and toes.³ Other clinical findings unique to acro-dynia include weakness, hypotonia, insomnia, ulcerative gingivitis, and loss of teeth.^{2,3} Kawasaki disease and acro-dynia are each associated with the appearance of an exanthem. As noted recently, the exanthem of Kawasaki disease is frequently concentrated in, or may be limited to, the perineum.^{1,4,5} While coronary artery aneurysms are not known to occur in acro-dynia, they are a well-recognized complication of Kawasaki disease that was observed in our patient.

Even though acro-dynia and Kawasaki disease share certain similarities, each exhibits a unique natural history and distinctive clinical manifestations. Although current epidemiologic and laboratory information suggests that Kawasaki disease may have an infectious origin,⁶ Drs Aschner and Aschner offer sound advice when they suggest that the search for other potential causative factors should continue. Until a causative agent is identified, the

might be the result some environmental insult cannot be excluded.

Age, Gender, and Metabolic Control in Children and Adolescents With Diabetes

Sir.—Adolescent girls with insulin-dependent diabetes mellitus (IDDM) have been found to have worse metabolic control than younger girls¹ and older women² with IDDM. However, the evidence is inconsistent regarding whether adolescent girls have worse control than adolescent boys.^{1,3} The sources of the purported poor metabolic control in adolescent girls are not clear, although several explanations have been proposed. It is widely believed that interactions of physiological concerns, social pressures, and physiological changes associated with adolescence contribute to the difficulties experienced by these individuals. Educational approaches to improving metabolic control are based in part on the hypothesized relationship between knowledge about diabetes and metabolic control. However, the evidence indicates that knowledge is unrelated, or even inversely related, to metabolic control.^{1,4}

Our study addressed these questions: (1) Do older girls demonstrate poorer metabolic control than boys and younger girls? (2) If older girls do have difficulty maintaining adequate control, is this due to inadequate knowledge about diabetes?

Patients and Methods.—The 23 girls and 17 boys with IDDM in this study ranged from 8 to 19 years of age (mean \pm SD, 13.7 \pm 2.2

years of age) and were recruited from a group of patients who received medical care at a juvenile diabetes clinic at the Duke University Medical Center, Durham, NC. Of the 40 subjects, 39 were white and 1 was black. Participation in this research was voluntary and was decided on the basis of parental and child consent. Subjects completed questionnaires in examination rooms during the course of their visits.

Diabetic control was assessed through the measurement of glycosylated hemoglobin levels (GlyHb) by affinity chromatography. This procedure was part of the regular clinic visit protocol. The GlyHb values typically ranged from 4.2% to 8.0% in individuals without diabetes. In our study, the GlyHb levels ranged from 6.8% (indicating good control) to 22.9% (indicating very poor control), with a mean value of 12.58% (4.15, SD).

A version of the test of diabetes knowledge by Johnson et al⁵ was used to assess knowledge of diabetes care. From the original set of 36 questions, 26 were chosen by a pediatric endocrinologist at the Duke University Medical Center Clinic as consistent with the treatment philosophy approach employed at the clinic. Johnson et al reported the split-half reliability of their measure to be .84, which is quite adequate. In our study, the scores ranged from 15 to 25 on this measure (mean, 20.55; SD, 2.17).

A two \times two analysis of covariance (ANCOVA) was used to evaluate the impact of sex (male, female) and age group (<13.9 years of age, \geq 13.9 years of age) on the dependent variable, GlyHb. The age group division was determined on the basis of a median split. Diabetes knowledge was evaluated and controlled for by including it as the covariate in the analysis.

Results.—The 4-year age-gender subgroups were composed of 13 younger girls (mean age, 12.3 years), 7 younger boys (mean age, 11.0 years), 10 older girls (mean age, 15.9 years), and 10 older boys (mean age, 15.2 years). The mean GlyHb values for younger boys and older boys with IDDM were 12.3% and 11.7%, respectively. For younger girls and older girls with IDDM the mean values were 10.6% and 16.3%, respectively. The ANCOVA indicated no significant contribution by either the covariate (ie, diabetes knowledge) or the main effect for sex. While the main effect for age group was significant ($F [1,35] = 4.21, P < .05$), this effect was explained entirely by the significant interaction of sex by the age group ($F [1,35] = 6.25, P < .02$). To evaluate the meaning of this interaction, simple main effects were calculated, indicating that older girls had worse metabolic control than younger girls ($F [1,35] = 14.01, P < .01$) and had control than older boys ($F [1,35] = 8.48, P < .01$) (Figure).

Comment.—The finding that metabolic control was worse in older girls is consistent with results from most prior

Age \times sex group interaction for metabolic control.

research.^{1,2} Furthermore, this pattern apparently cannot be explained by a lack of knowledge about diabetes care. Several other investigators also have reported knowledge to be unrelated, or even inversely related, to diabetic control.^{1,4} Factors other than self-care knowledge, then, must be contributing to the older girls' difficulties with diabetes. It has been suggested that the social demands and/or hormonal changes that accompany puberty in girls may lead to diabetes management problems. If the poor control is largely due to hormonal factors, changes in the degree of adherence to a health care regimen may have only minimal impact on the disease.

Noncompliance among these individuals, then, may arise partly out of the feeling that compliance is a futile endeavor, since their diabetes is experienced as an unmanageable disease. Additionally, although the gender differences reported here are not explained by this research, it is of note that decreased sensitivity to insulin has been found in pubertal children with and without diabetes.^{6,7} Clearly, it is important to focus future research efforts on adolescent girls with diabetes to try to determine the source of their difficulties with their illness and, if possible, to help them achieve better metabolic control.

Hyperglycemic Acidosis With Mortality in Kearns-Sayre Syndrome

Sir.—Kearns-Sayre syndrome (KSS) is a rare multisystemic disorder, usually described as the clinical triad of chronic progressive ophthalmoplegia, retinitis pigmentosa, and cardiomyopathy.¹⁻³ There is a pathologic degeneration of the central nervous system (ie, spongiform degeneration of the brain) and skeletal and pancreatic abnormalities.^{4,5} Sudden death in patients with KSS has been primarily attributed to the cardiac conduction defects and cardiomyopathy.³

Recently, the association of chemical diabetes and hyperglycemic acidotic coma has been documented in the ophthalmology literature.⁶ We describe three patients with KSS who we believed died secondary to complications related to KSS and hyperglycemic coma. We would like to bring this potentially devastating problem to the attention of the pediatrician.

Patient Reports.—PATIENT 1.—A 14-year-old boy was first seen at 10 years of age with bilateral ptosis, proximal skeletal myopathy, and external ophthalmoplegia. At that time, the results of his cardiac examination were normal, but his electrocardiogram demonstrated left-axis deviation and a right bundle branch block pattern. Three years later, the patient developed a 2:1 and 3:1 block associated with syncope. A permanent demand ventricular pacemaker was inserted, and clinical improvement resulted. During that hospitalization, the diagnosis of KSS was made.

Five months later, prednisone therapy was initiated, 100 mg every other day orally, for progressive muscle weakness. Fifteen days later, the patient suddenly collapsed and was unresponsive on arrival

at the University of Miami/Jackson Memorial Hospital emergency department. His mother gave the medical history of polyuria and polydipsia 2 days prior to admission. The electrocardiogram showed normal ventricular pacing. The serum glucose level was greater than 27.8 mmol/L. The blood gas analysis revealed a pH level of 6.88 and a base deficit of -25. Shortly thereafter, the patient had a cardiopulmonary arrest and could not be resuscitated.

PATIENT 2.—An 8½-year-old boy presented with the clinical triad of KSS, complete atrioventricular block, and syncope. A permanent epicardial pacemaker was surgically implanted. At that time a muscle biopsy revealed the characteristic "ragged red fiber myopathy," and the diagnosis of KSS was confirmed.

Over the next 4 years, the patient experienced further growth retardation, progressive ataxia, and proximal muscle weakness. When the patient was 12 years of age, a neurologist initiated prednisone treatment, 25 mg/d, for progressive muscle weakness. Within the next 4 days, polydipsia, polyuria, and polyphagia ensued. A cardiopulmonary arrest occurred, and the patient was taken to the University of Miami/Jackson Memorial Hospital emergency department. An electrocardiogram demonstrated normal ventricular pacing. The arterial blood gas analysis demonstrated a pH level of 6.97 with a base deficit of -25; the serum glucose level was 53.7 mmol/L. Medical treatment failed to correct the metabolic derangement and maintain adequate cardiac output. The patient died within 24 hours of admission.

PATIENT 3.—A 9-year-old boy with KSS required a ventricular-demand pacemaker because of presyncope attributed to complete heart block. Progressive skeletal myopathy caused the patient to be debilitated, and steroid therapy was initiated. He collapsed in school and was taken to a local hospital emergency department. Initially, the diagnosis of pacemaker failure was entertained. However, a random serum glucose level was 57.7 mmol/L; glucose was present in his urine but ketonemia was not evident. The arterial blood gas analysis demonstrated a severe metabolic acidosis. Normal pacemaker function was present on the electrocardiogram. Despite aggressive therapy, the patient died within 6 hours.

Comment.—Over the past 12 years, there have been at least nine reported cases of KSS with associated chemical diabetes, defined by an abnormal glucose tolerance level and/or an elevated fasting blood glucose level.^{4,6,7} To date, there has been no satisfactory explanation for the appearance of this hyperglycemia.

Postmortem examinations of the three patients described herein revealed myocardial histologic changes characteristic of KSS: irregular muscle fibers with large nuclei and fatty and fibrotic infiltration of the conduc-

tion system. Of interest was the pathologic description of the pancreas in two patients; there was a decrease in the number of pancreatic islet cells, along with abnormal edematous mitochondria, fatty infiltration, and fibrosis. The third case demonstrated abnormally large islet cells.

It is known that KSS is associated with pathological degeneration of the myocardial conduction system, the central nervous system, the musculoskeletal system, and, as evidenced in these cases, in the pancreatic cells. The abnormality in the pancreas could result in a predisposition to hyperglycemia.

It is well appreciated that steroid-induced hyperglycemia is caused by an increase in gluconeogenesis and a decreased glucose utilization,⁸ which can result in significantly elevated blood glucose levels. This differs from insulin-dependent or type I diabetes, which is defined as a total deficient endogenous insulin state.⁹ This occurs when a sufficient number of beta cells are destroyed by various causes (ie, autoimmune, viral, or toxic destruction) to result in a decrease in insulin secretion so that hyperglycemia occurs.¹⁰

In the presence of pathologic degeneration of pancreatic islet cells as exhibited in these reported cases, it is reasonable to assume that the steroids resulted in the hyperglycemia and metabolic abnormalities. Their deleterious effects superimposed on the central nervous system and cardiac pathologic findings could have resulted in their death.

Physicians caring for patients with KSS should routinely measure fasting serum glucose levels and perform a glucose tolerance test.^{4,6,7} Special attention should focus on any symptoms suggestive of hyperglycemia, such that aggressive management can proceed if indicated. We recommend that steroids not be used in the management of the associated skeletal myopathy seen in KSS due to its diabetogenic effects.

Finally, if a patient with KSS has a sudden catastrophic event, immediate attention should focus on pancreatic glucose function and the resulting metabolic derangement as well as cardiac and cerebral abnormalities.

Complex Congenital Heart Disease After In Vitro Fertilization

Sir.—Congenital heart disease is a rare complication in newborns conceived by in vitro fertilization and embryo transfer.¹⁻³ We describe a patient with a complex congenital heart disease born after this procedure. The mother was 28 years old and had had previous abortions that caused infertility. The blastocystic implantation was accomplished in Rome, at another institution. The newborn, a chromosomically normal female, was born at the 34th week of gestation following an uncomplicated pregnancy. Delivery was normal, and birth weight was 2300 g. Cyanosis was noted at birth, and cardiac catheterization revealed pulmonary atresia with a large ventricular septal defect. The pulmonary arteries were supplied by a ductus arteriosus, the aorta arose completely from the right ventricle surrounded by a muscular infundibulum, and a persistent left superior vena cava drained into the left atrium through an unroofed coronary sinus. The patient underwent a right Blalock-Taussig shunt as a neonate, and the definitive correction was successfully performed when she was 20 months of age, with a Rastelli procedure involving closure of the ventricular septal defect and placement of a valved conduit between the right ventricle and the confluence of the pulmonary arteries. Six children with congenital heart

isease born after in vitro fertilization and embryo transfer have been previously described.¹⁻³ Four patients had transposition of great arteries,^{1,2} one had ventricular septal defect,² and the last one was affected by tetralogy of Fallot.³ To our knowledge, complex congenital heart malformation such as in our case has not been reported yet. Further studies on outcomes of in vitro fertilization are needed to determine the exact incidence and types of congenital anomalies and the possible role of teratologic factors associated with this procedure.

Hirschsprung's Disease and Ocular Autonomic Nerve Function

Purpose.—We pharmacologically assessed the ocular autonomic nervous systems of 10 children with Hirschsprung's disease, using 0.1% pilocarpine nitrate and 0.5% phenylephrine hydrochloride. Our results did not indicate any significant abnormality in the ocular autonomic nervous systems of children with Hirschsprung's disease, compared with those of normal controls.

Hirschsprung's disease is a congenital anomaly of innervation affecting the intrinsic plexuses of Auerbach and Meissner in the lower gut.¹ These autonomic plexuses are derived from the cranio-cervical neural crest.² The superior cervical ganglion (sympathetic) and the ciliary ganglion (parasympathetic) of the eye are also derived from the cranio-cervical neural crest.³

Patients and Methods.—Ten children with Hirschsprung's disease, two girls and eight boys, between 4 and 14 years of age were examined. All children had histologically proved Hirschsprung's disease. Twenty age- and sex-matched controls were obtained from our pediatric ophthalmology screening clinics.

Baseline measurements included visual acuity, orthoptic assessment, and resting pupil size, under standard conditions of brightness (luminance, 300 apostilbs). Ocular autonomic nerve function was investigated by testing for autonomic denervation

hypersensitivity of the iris. Pupil cycle measurements are unsatisfactory in the pediatric age group, in our experience. Pilocarpine, in a 0.1% solution, was used to determine the pupillary parasympathetic status, and 0.5% phenylephrine hydrochloride was used to determine its sympathetic status. Both of these drugs are direct acting and mimetic. Drug instillation was fully randomized in a double-blind manner, and normal saline solution was used as a control in the nontested eye. One drop (0.05 mL) was instilled into the lower conjunctival fornix, and 45 minutes later the pupil diameter was measured using a commercially available set of black circles, with the patient's eyes focused for distance.

At the patient's first visit 0.1% pilocarpine was placed in the conjunctival sac of one eye, and normal, sterile saline solution was placed in the conjunctival sac of the other eye. One month later the process was repeated using 0.5% phenylephrine as the active pharmaceutical agent. The children were screened for ocular evidence of von Recklinghausen's disease, Down syndrome, and Waardenburg's syndrome, all known associations of Hirschsprung's megacolon.

Results.—Our results indicated that neither 0.1% pilocarpine nor 0.5% phenylephrine cause any significant effect on pupil diameter compared with administration of normal saline solution. A positive response in denervation hypersensitivity typically results in a 3- to 4-mm change in pupil diameter.⁴ There was no significant difference between the responses of the control group compared with children with Hirschsprung's disease. Any observed difference is within the realm of experimental error and, therefore, *t* tests and confidence intervals were not indicated.

Comment.—Wilhelm first described the neural crest in 1868 and later reported the migration of these cells into spinal and cranial ganglia, including the superior cervical ganglion and ciliary ganglion of the eye. It has since been shown experimentally that the intrinsic plexuses of the colon are derived from the same cranio-cervical neural crest.³ Neuroblasts develop in the intestinal tract by cephalocaudal migration along vagal trunks through the intestine. Hirschsprung's disease is a neurocristopathy resulting from an abnormality in migration of these neural crest precursors of the myenteric plexuses.

Ocular neurocristopathies associated with Hirschsprung's megacolon are well documented and include Waardenburg's syndrome, Marcus-Gunn ptosis, and von Recklinghausen's disease.⁵ Because of these associations it was theoretically considered that

children with Hirschsprung's disease might exhibit abnormal ocular autonomic function, as the ocular autonomic nervous system develops embryologically from the same cranio-cervical neural crest as the intrinsic ganglia of the gut.

The principle of denervation hypersensitivity, defined as an increased response of a tissue to a chemical neurotransmitter or agonist and following deprivation of its nerve supply, may be applied in the assessment of ocular autonomic nerve function.⁶ Pupil diameter represents the relative balance of autonomic activity in the anterior segment of the eye; sympathetic nerves affect pupillary dilation via the dilator pupillae, and parasympathetic nerves affect pupillary constriction via the sphincter pupillae.

Little is known about testing ocular autonomic nerve function in children, but our results and clinical experience suggest that it differs little from that of adults. There were no documented local or systemic adverse reactions in any of the children tested.

Analysis of the results showed no evidence of a specific ocular autonomic neuropathy in children with Hirschsprung's disease. Further investigations may elicit nonocular neuropathy in other systems of children with Hirschsprung's disease.

The Human Immunodeficiency Virus–Infected Infant

A Diagnostic Dilemma

Congenital infection with the human immunodeficiency virus (HIV) has a profound effect on growth and development of the newborn. As is typical for congenitally acquired infections, the symptoms in the young infant are distinct from those observed in older children and adults. Although HIV-infected infants have been stud-

See also p 1147.

ied for half a dozen years,^{1,2} and detailed descriptions of the natural course have appeared in the literature,³⁻⁵ many issues related to maternal-fetal transmission are poorly understood. In this issue of *AJDC*, Johnson and coworkers⁶ report a prospective study of 20 infants born in the Baltimore, Md, area to HIV-seropositive women. The infants were observed for a minimum of 18 months to determine the natural history of congenital HIV infection. The study fails, however, as did previous studies of congenital HIV infection, to address the maternal-fetal factors that affect virus transmission from the mother to the offspring and to take the guesswork out of diagnosing HIV infection in the very young infant.

Despite the close contact between mother and fetus in utero, the prospects of virus-loaded macrophages migrating across the placenta, and the likelihood of exposure of the infant during the birthing process to maternal blood and secretions, only 25% to 50% of the offspring of HIV-infected mothers appear to be infected by the virus. Are there some yet unknown protective mechanisms involved? On the other hand, this estimate may have to be revised because of the recent observation that HIV infection can be dormant for years without active viral replication.^{7,8} Without an animal model

to study maternal-fetal transmission, many of the more fundamental questions related to vertical transmission of HIV from the mother to the fetus cannot be answered with certainty. A number of pressing issues, however, must be addressed immediately. First, we have to find socially and legally acceptable ways to identify all HIV-seropositive pregnant women, a strategy considered essential for protecting the fetus from other sexually transmitted infectious diseases. Without identifying infants at risk, innovative steps to prevent maternal-fetal transmission cannot be taken, and optimal care of the affected infants cannot be provided. The experience from Baltimore shows that if approached in a sensitive way, pregnant women with known risk factors will consent almost without exception to HIV testing.

Second, we need to sort out the major events that play a role in the transfer of HIV from the mother to the fetus. Human immunodeficiency virus has been cultured from fetal tissue at as early as 8 weeks of gestation,⁹ suggesting that at least some fetuses are exposed to HIV during early pregnancy. Little is known about the placenta as a barrier between the maternal and fetal circulation, and many questions remain as to the importance of an active transport across the placenta. Can free virus penetrate or directly infect the syncytiotrophoblast? Do HIV-infected macrophages or CD4⁺ lymphocytes actively cross the placenta? Can virus cross the placenta by forming complexes with specific antibody that binds via the Fc receptors to phagocytic cells? How frequent and how important are maternal-fetal transfusions at the time of delivery?

A third area that needs to be addressed concerns maternal factors that may play a role in vertical trans-

mission of HIV. Offspring of women with high antibody titers to gp120 have a lower incidence of infection than offspring of women with depressed levels.¹⁰ It has been proposed—but not documented—that free virus in the maternal circulation facilitates vertical transmission of HIV to the fetus.

Last, and most important, we have not yet developed the skills to clearly differentiate between infected and noninfected offspring of HIV-seropositive mothers. New diagnostic methods are urgently needed. The presence of maternally derived HIV-specific antibody in the infant's blood makes interpretation of serologic assays difficult. It may take up to 15 months for passively acquired antibodies to disappear from the infant's circulation, too long a wait for the parents and the infant's physician. The observation that some HIV-infected infants never produce antibody to HIV makes it even more difficult to interpret the results of antibody testing.

Promising new techniques designed to detect the virus or to assess the infant's own immune response to HIV have been introduced and tested in small pilot studies. Quantitative analysis of serum antibodies to HIV suggests infection of the infant if the initial drop in antibody titer after birth is followed by a persistent rise. Similarly, the appearance of new bands in serially tested serum using Western blot analysis, the detection of HIV-specific IgM or IgG subclass antibody not present in maternal serum,¹¹ or the demonstration of *in vitro* synthesis of HIV-specific antibody by peripheral blood lymphocytes from infants at risk¹² may signal a specific immune response by the infant and indicate infection with HIV. A positive culture, a technique limited to major medical centers, is considered the gold standard for confirming the diagnosis.

of HIV infection. The success rate for obtaining positive cultures from HIV-infected infants varies and depends on the experience of the investigators, the type of cell line used in the co-culture system, and the number of infective viral particles placed in the culture system. Under optimal conditions, more than 90% of seropositive older children and adults turn out to be culture positive; the success rate in infants may be less. Amplification of part of the HIV genome by the polymerase chain reaction followed by hybridization with a specific probe appears to be a most promising technique for rapid and highly specific detection of early HIV infection in the neonate.^{13,14} However, at present, only a few laboratories have the experience to appropriately interpret the results. Broad use of these new techniques will be vital for early diagnosis, systematic evaluation of new antiviral drugs, and,

finally, the prevention of maternal-fetal transmission of HIV.
